# TRANSACTIONS

OF THE

# AMERICAN SOCIETY

OF

# CIVIL ENGINEERS

(INSTITUTED 1852)

VOLUME 95

1931

Edited by the Secretary, under the direction of the Committee on Publications.

Reprints from this publication, which is copyrighted, may be made on condition that the full title of Paper, name of Author, and page reference are given.

NEW YORK
PUBLISHED BY THE SOCIETY

1931

Entered according to Act of Congress, in the year 1931, by the AMERICAN SOCIETY OF CIVIL ENGINEERS, in the office of the Librarian of Congress, at Washington.

NOTE.—This Society is not responsible for any statement made or opinion expressed in its publications.

# CONTENTS

## PAPERS

| No. | | PAGE |
|---|---|---|
| 1763 | **NIAGARA POWER.** | |
| | By **Norman R. Gibson** | 1 |
| | Discussion: | |
| | By THOMAS H. HOGG | 29 |
| | FRANK M. WILLIAMS | 34 |
| | CHARLES KELLER | 36 |
| | WILLIAM KELLY | 41 |
| | R. D. JOHNSON | 43 |
| | GLEN E. EDGERTON | 44 |
| | F. P. WILLIAMS | 47 |
| | LEWIS B. STILLWELL | 48 |
| | NORMAN R. GIBSON | 50 |
| 1764 | **REGULATION OF LEVELS, FLOW, AND NAVIGATION, NIAGARA RIVER: SUMMARY AND CONCLUSIONS OF VARIOUS STUDIES.** | |
| | By **George B. Pillsbury** | 51 |
| | Discussion: | |
| | By ROBERT E. HORTON | 63 |
| | LYNN L. DAVIS | 75 |
| | THERON M. RIPLEY | 79 |
| | E. W. LANE | 80 |
| | F. G. RAY | 81 |
| | GEORGE B. PILLSBURY | 83 |
| 1765 | **EXPERIMENTAL RESEARCH ON VIBRATION DAMPERS AND INSULATORS.** | |
| | By **Stephen E. Slocum** | 85 |
| | Discussion: | |
| | By J. P. DEN HARTOG | 106 |
| | FRANCIS G. TATNALL | 108 |
| | W. M. DAWLEY | 110 |
| | STEPHEN E. SLOCUM | 125 |
| 1766 | **HIGH DAMS: A SYMPOSIUM** | 129 |
| | **PAST EXPERIENCE WITH HIGH DAMS AND OUTLOOK FOR THE FUTURE.** | |
| | By **A. J. Wiley** | 130 |
| | **CLASSIFICATION, SELECTION, AND ADAPTATION OF HIGH DAMS.** | |
| | By **D. C. Henny** | 139 |

| No. | | PAGE |
|---|---|---|
| | **HIGH DAMS: THE VIEWPOINT OF THE GEOLOGIST.** | |
| | By F. L. Ransome | 149 |
| | **CONSTRUCTION METHODS AND PLANT LAYOUT AT COOLIDGE DAM, IN ARIZONA.** | |
| | By J. G. Tripp | 159 |
| | Discussion: | |
| | By F. G. Switzer | 169 |
| | Fred A. Noetzli | 171 |
| | Edward Godfrey | 174 |
| | B. F. Jakobsen | 179 |
| | Allen Hazen | 183 |
| | H. de B. Parsons | 184 |
| | P. Wilhelm Werner | 186 |
| | C. A. P. Turner | 188 |
| | F. W. Hanna | 192 |
| | H. F. Dunham | 195 |
| | Lars R. Jorgensen | 196 |
| | William P. Creager | 197 |
| | L. F. Harza | 198 |
| | A. Floris | 200 |
| | Joseph Wright | 205 |
| | A. J. Wiley | 212 |
| | D. C. Henny | 225 |
| | J. G. Tripp | 230 |
| 1767 | **ADJUSTMENT OF TRANSIT AND STADIA TRAVERSES.** | |
| | By Howard S. Rappleye | 232 |
| | Discussion: | |
| | By Lowell O. Stewart | 237 |
| | Paul H. Underwood | 237 |
| | F. H. Peters | 240 |
| | H. Parry | 241 |
| | Howard S. Rappleye | 243 |
| 1768 | **CONSTRUCTION OF THE JAMES RIVER BRIDGE PROJECT.** | |
| | By R. C. Wilson and Herbert B. Pope | 244 |
| | Discussion: | |
| | By Wilson T. Ballard | 262 |
| | William Willoughby | 266 |
| | R. C. Wilson and Herbert B. Pope | 268 |
| 1769 | **FACTORS GOVERNING THE LOCATION OF AIRPORTS.** | |
| | By Donald M. Baker | 269 |
| | Discussion: | |
| | By Stephen Child | 279 |
| | Morris Knowles | 281 |
| | George D. Burr | 283 |
| | N. H. Angell | 285 |

| No. | | PAGE |
|---|---|---|
| | J. Ogden Marsh | 286 |
| | Archer R. Norcross | 287 |
| | John Nolen | 288 |
| | S. N. Grimm | 290 |
| | R. U. St. John | 292 |
| | John F. Partridge | 296 |
| | William J. Fox | 296 |
| | Perry A. Fellows | 308 |
| | W. W. Crosby | 308 |
| | E. K. Smith | 309 |
| | Clyde M. Wood | 311 |
| | Donald M. Baker | 313 |
| 1770 | **SPILLWAY DISCHARGE CAPACITY OF WILSON DAM.** | |
| | **By Louis G. Puls** | 316 |
| | Discussion: | |
| | By Cecil E. Pearce | 330 |
| | J. H. Jones | 332 |
| | Louis G. Puls | 333 |
| 1771 | **COMPLETION OF MOFFAT TUNNEL OF COLORADO.** | |
| | **By Clifford Allen Betts** | 334 |
| | Discussion: | |
| | By J. Vipond Davies | 372 |
| | R. H. Keays | 374 |
| | A. A. Eremin | 375 |
| | Clifford Allen Betts | 377 |
| 1772 | **RAINFALL CHARACTERISTICS AND THEIR RELATION TO SOILS AND RUN-OFF.** | |
| | **By C. S. Jarvis** | 379 |
| | Discussion: | |
| | By George S. Bliss | 424 |
| | Brehon B. Somervell | 424 |
| | Jesse W. Shuman | 426 |
| | Clinton L. Bogert | 432 |
| | R. W. Powell | 432 |
| | Glen N. Cox | 439 |
| | C. R. Pettis | 440 |
| | George C. Danforth | 444 |
| | C. S. Jarvis | 449 |
| 1773 | **BALDWIN FILTRATION PLANT, CLEVELAND, OHIO.** | |
| | **By J. W. Ellms, G. W. Hamlin, A. G. Levy, and J. E. A. Linders** | 455 |
| | Discussion: | |
| | By S. M. Van Loan | 519 |
| | Harry N. Jenks | 519 |
| | James H. Herron | 528 |
| | E. Sherman Chase | 529 |
| | J. W. Ellms, G. W. Hamlin, A. G. Levy, and J. E. A. Linders | 530 |

| No. | | PAGE |
|---|---|---|
| 1774 | **LAMINATED ARCH DAMS WITH FORKED ABUTMENTS.** | |
| | By **Fred A. Noetzli** | 533 |
| | Discussion: | |
| | By LARS R. JORGENSEN | 565 |
| | WILLIAM CAIN | 566 |
| | B. F. JAKOBSEN | 568 |
| | P. WILHELM WERNER | 572 |
| | H. B. MUCKLESTON | 573 |
| | FREDRIK VOGT | 574 |

# NIAGARA POWER[1]

By Norman R. Gibson,[2] M. Am. Soc. C. E.

With Discussion by Messrs. Thomas H. Hogg, Frank M. Williams, Charles Keller, William Kelly, R. D. Johnson, Glen E. Edgerton, F. P. Williams, Lewis B. Stillwell, and Norman R. Gibson

## Synopsis

In preparing this paper it has seemed best to present, first, in barest outline, a general picture of the engineering phases of the power plants at Niagara Falls, illustrating their principal characteristics and tracing their development as the art has progressed; next, to discuss some of the newer problems connected with power in the Niagara River; and, finally, to direct attention to the significance of Niagara power in the industrial and social development of two extensive and important territories in two countries. In order to avoid needless repetition, detail descriptions of the plants are not given, but instead a classified bibliography is appended for such further information as may be desired.

## Early Power Plants

The small power plants built early in the Nineteenth Century have long since disappeared, leaving but little evidence of their one-time existence. Power development at Niagara Falls emerged from the dim past about 1853, when Messrs. Caleb S. Woodhull, Walter Bryant, and their associates commenced the construction of the hydraulic canal, about one mile long and extending from Port Day on the American side of the river just above the Falls to a point on the Gorge about a mile below the Falls. This canal, when enlarged to its present dimensions, was destined to become a part of one of the most important plants existing to-day. It was first put into operation

[1] Presented at the meeting of the Power Division, Buffalo, N. Y., July 19, 1928.

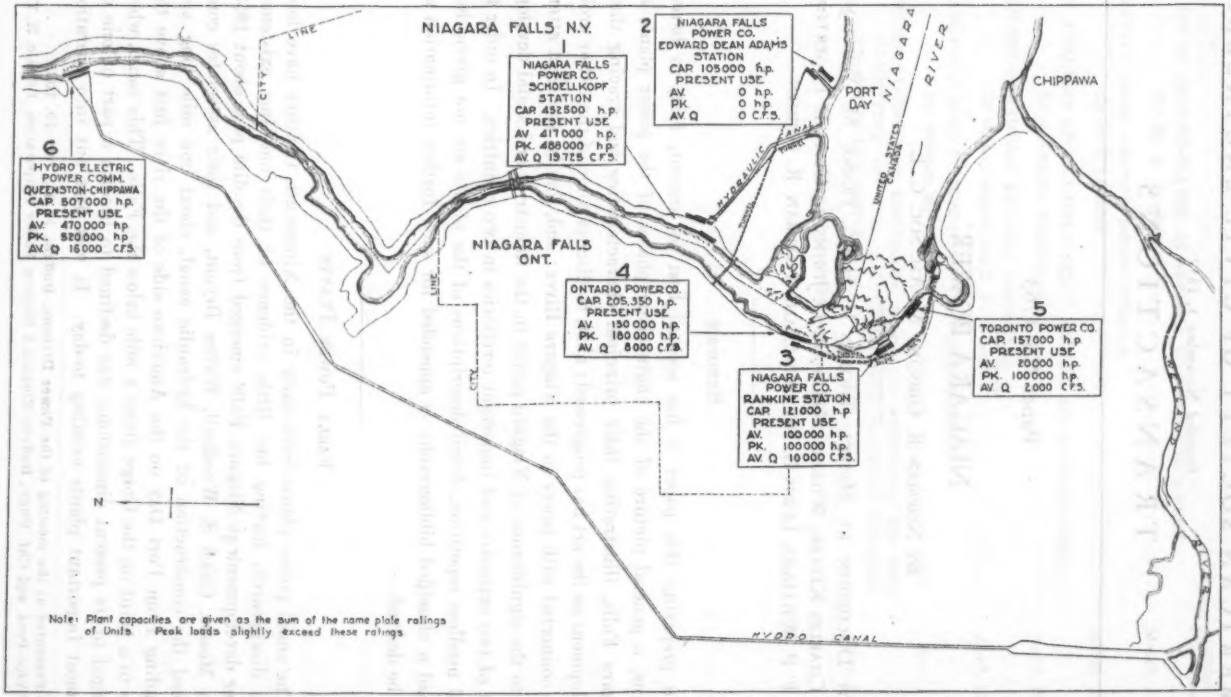

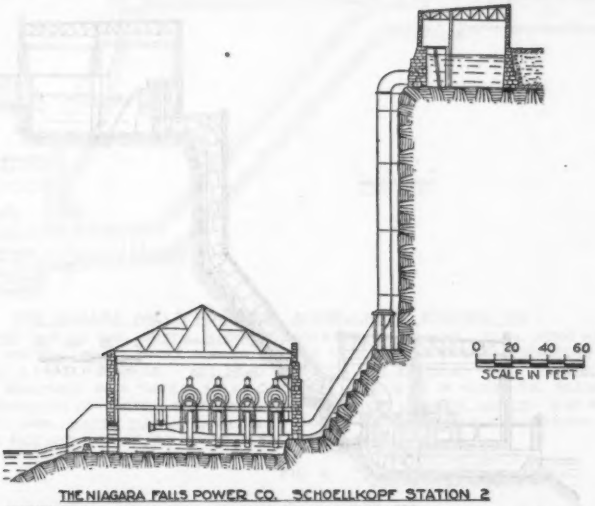

FIG. 1.—MAP SHOWING LOCATION OF EXISTING NIAGARA POWER PLANTS.

about 1875, when it had a cross-section varying from 20 to 36 ft. in width and about 8 to 10 ft. in depth. Since then it has been used continuously and enlarged from time to time until it has now reached a size of 100 ft. wide by about 20 ft. deep.

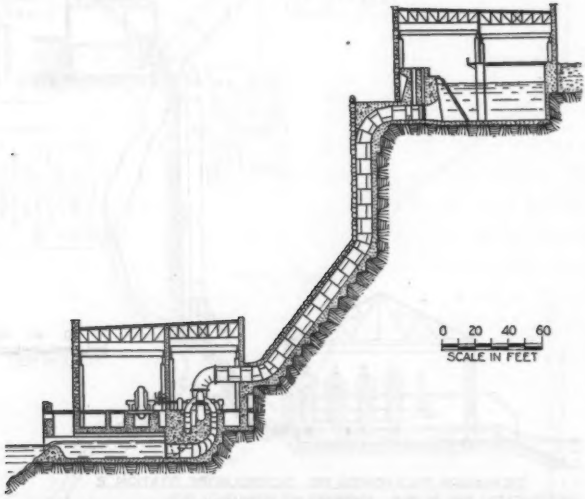
## Present Power Plants

To-day (1928), there are six major hydro-electric generating stations at Niagara Falls, having a total installed capacity of 1 547 850 h.p. As shown in Fig. 1, four of these stations, aggregating an installed capacity of 990 350 h.p., are on the Canadian side of the river, and two, with an installation of 557 500 h.p., are on the American side. The ownership and control of all these plants are vested in two organizations, the two plants on the American side and one of those in Canada being owned or controlled by The Niagara Falls Power Company, a New York corporation, and the remaining three plants on the Canadian side being under the Hydro-Electric Power Commission of Ontario.

THE NIAGARA FALLS POWER CO. SCHOELLKOPF STATION 2

CONSTRUCTED: 1895 TO 1904 ABANDONED 1923 DEMOLISHED 1925.
INSTALLATION (1921) 4-UNITS 2300 H.P. 4-2900 H.P. 1-2800 H.P. 250 R.P.M. TOTAL 9 UNITS 23600 H.P.
TURBINES: HORIZONTAL SHAFT, DOUBLE RUNNER, GEYLIN, JONVAL AND FRANCIS TYPES.
GENERATORS: EARLIER INSTALLATIONS INCLUDED A.C. UNITS AT 11000 VOLT, 3 PHASE, 30 CYCLES AND 2200 VOLT SINGLE PHASE 125 CYCLES. (1921) 4-750 KW 300 VOLT D.C., 2-875 KW 160 VOLT D.C., 8-1000 KW 300 VOLT D.C. 4-750 KW 350 VOLT D.C. TWO GENERATORS DIRECTLY COUPLED TO TURBINE SHAFT. NET HEAD: ABOUT 210 FT. UNIT EFFICIENCY: 80%.
PENSTOCKS: PLATE STEEL, 1-8'-0" DIAM. 240 FT. LONG, 2-11'-0" DIAM. 270 FT. LONG. SLIDING STEEL HEAD GATES. WATER SUPPLY: CANAL 100 FT. WIDE BY 20 FT. DEEP, AND 4500 FT. LONG FROM INTAKE ABOUT ONE MILE ABOVE FALLS. SUPPLYING ALSO STATIONS 3A AND 3B.

Fig. 2



*Schoellkopf Station.*—The hydraulic canal, Fig. 1, was purchased in 1877 by Jacob F. Schoellkopf and others who, a year later, organized The Niagara Falls Hydraulic Power and Manufacturing Company, using the canal to

Fig. 1.—Map Showing Location of Existing Niagara Power

supply water to wheels in mills located at the top of the high bank along the Gorge. The water-wheels were placed in the bottom of shafts or pits sunk beneath the mills at various depths, and utilized from 25 to 86 ft. of the total 215 ft. available head.

Following early experimental stations from 1880 onward, The Niagara Falls Hydraulic Power and Manufacturing Company constructed, in 1881, its first commercial hydro-electric generating station, which was known as Station No. 1. It had a capacity of 2 000 h.p. generated by direct-current dynamos operated by rope drives from water-wheels. This station was abandoned in 1904.

Station No. 2 of this Company (Fig. 2) was begun in 1895, completed about 1904, abandoned in 1921, and demolished in 1925. Originally, it had a total of fifteen hydro-electric units with an aggregate capacity of 33 900 h.p. These units were supplied with water from the hydraulic canal by three steel-plate penstocks, each of which fed from four to six units. In 1914, six units and one penstock were abandoned, leaving nine units having an aggregate capacity of 23 600 h.p.

THE NIAGARA FALLS POWER CO. SCHOELLKOPF STATION 3A

CONSTRUCTED: 1905 TO 1914. INSTALLATION: 13 - 10000 H.P. UNITS, 300 R.P.M., TOTAL 130000 H.P.
TURBINES: HORIZONTAL SHAFT, DOUBLE RUNNER, FRANCIS TYPE, SCROLL CASE.
GENERATORS: 8000 KVA., 12000 VOLTS, 3 PHASE, 25 CYCLES. NET HEAD: 210 FT. UNIT EFFICIENCY: 86%.
PENSTOCKS: PLATE STEEL, 260 FT. LONG, 9'-0" DIAM., GATE VALVES. WATER SUPPLY: CANAL 100 FT. WIDE BY 20 FT. DEEP, 4500 FT. LONG FROM INTAKE ABOUT ONE MILE ABOVE FALLS, SUPPLYING ALSO STATION 3B.

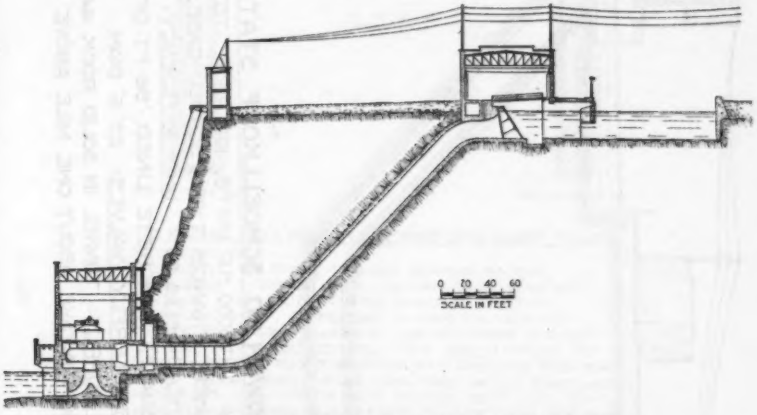


FIG. 3.

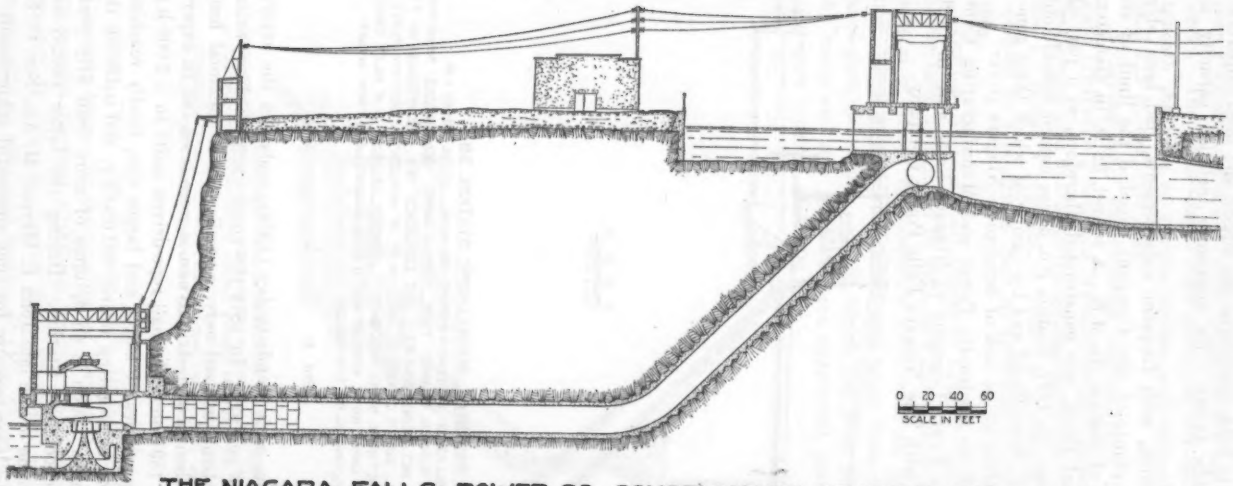
About 1903, The Niagara Falls Hydraulic Power and Manufacturing Company began the construction of Section A of its Station No. 3 (Fig. 3), to contain thirteen 10 000-h.p. units. This, together with the addition of Section B (Fig. 4), having three 37 500-h.p. units constructed during the years 1918 to 1920, and Section C (Fig. 5), with three 70 000-h.p. units con-

structed in the period, 1922 to 1924, constitutes the largest and most important plant on the American side to-day. Its aggregate installed capacity is 452 500 h.p.

The hydraulic canal which, with frequent enlargements, had been able to supply water to all the plants of this Company, reached the limit of its capacity after the addition of Station No. 3-B. A tunnel, 32 ft. in diameter, from Port Day to the Canal Basin, was constructed, therefore, as a part of the Station No. 3-C addition. In 1927, Station No. 3 was named Schoellkopf Station in honor of Jacob F. Schoellkopf and his family of which three generations have devoted themselves to the task of developing Niagara power.

In 1910, The Niagara Falls Hydraulic Power and Manufacturing Company became the Hydraulic Power Company of Niagara Falls, and, in 1918, the latter was consolidated with The Niagara Falls Power Company.

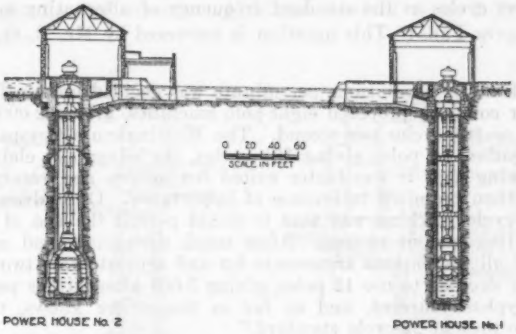


THE NIAGARA FALLS POWER CO. SCHOELLKOPF STATION 3B

CONSTRUCTED: 1918 TO 1920. INSTALLATION: 3-37500 H.P. UNITS, 150 R.P.M., TOTAL 112500 H.P. TURBINES: VERTICAL SHAFT, SINGLE RUNNER, FRANCIS TYPE, SCROLL CASE. GENERATORS: 32500 KVA. 12000 VOLTS, 3 PHASE, 25 CYCLE. NET HEAD: 213.5 FT. UNIT EFFICIENCY: 91%. PENSTOCKS: 381 FT. LONG, 15'-6" DIAM., SOLID ROCK TUNNEL, 320 FT. CONCRETE LINED, 61 FT. OF HORIZONTAL SECTION PLATE STEEL ENCASED IN CONCRETE. SECTIONAL STEEL HEADGATE. JOHNSON VALVES: 15'-6" INLET DIAM., 10'-6" OUTLET DIAM. WATER SUPPLY: CANAL 100 FT. WIDE BY 20 FT. DEEP 4500 FT. LONG FROM INTAKE ABOUT ONE MILE ABOVE FALLS, SUPPLYING ALSO STATION 3A.

FIG. 4.

The Schoellkopf Station, as it stands to-day (1928), embodies the experience and progress of half a century. In 1875 the small canal feeding waterwheels in mills along the bank utilized only a small part of the total head available. After 1880 the then new electric dynamos were tried out in experimental stations, and from 1891 onward small rope-driven units in a 2 000-h.p. station were followed by machines of larger and larger size, finally reaching 70 000 h.p. each in a station aggregating nearly 500 000 h.p. and utilizing the full 215 ft. of head available. Such is an epitome of more than fifty years of development in the Schoellkopf Station. During the latter twenty-five years of that period, the name of the late John L. Harper, M. Am. Soc. C. E., stands out as responsible in large measure for such successful achievement.



## THE NIAGARA FALLS POWER CO. SCHOELLKOPF STATION 3C

CONSTRUCTED: 1921 TO 1924. INSTALLATION: 3-70000 H.P. UNITS, 107 R.P.M. TOTAL 210000 H.P. TURBINES: VERTICAL SHAFT, SINGLE RUNNER, FRANCIS TYPE, SCROLL CASE. GENERATORS: 65000 KVA. 12000 VOLTS, 3 PHASE, 25 CYCLE. NET HEAD: 213.5 FT. UNIT EFFICIENCY: 92%. PENSTOCKS: 600 FT. LONG, 21'-0" DIAM., SOLID ROCK TUNNEL, 504 FT. CONCRETE LINED, 96 FT. OF HORIZONTAL SECTION PLATE STEEL ENCASED IN CONCRETE. BUTTERFLY VALVES: 23'-6" DIAM. JOHNSON VALVES: 21'-0" INLET DIAM., 14'-0" OUTLET DIAM. WATER SUPPLY: TUNNEL IN SOLID ROCK 4400 FT. LONG, 32'-0" DIAM. HORSESHOE SHAPE, CONCRETE LINED, FROM INTAKE ABOUT ONE MILE ABOVE FALLS. TUNNEL AND CANAL INTERCONNECTED.

FIG. 5.

*Edward Dean Adams Station.*—The Niagara Falls Power Company was created in 1886, under the name of The Niagara River Hydraulic Tunnel Power and Sewer Company, the name being changed in 1889. At that time it was debated whether the Company should develop hydraulic power to be delivered to mills located along its waterways, or pneumatic power for transmission to industrial districts and even to Buffalo, N. Y. This question was settled by the rapid development of electrical power which definitely displaced both the other proposals.

THE NIAGARA FALLS POWER CO. EDWARD DEAN ADAMS STATION.
POWER HOUSE No. 1
CONSTRUCTED: 1890 TO 1900. TURBINES REMODELED 1910 TO 1912.
INSTALLATION: 10-5000 H.P. UNITS, 250 R.P.M., TOTAL 50000 H.P.
TURBINES: VERTICAL SHAFT, SINGLE RUNNER, FRANCIS TYPE. CYLINDRICAL GATES. GENERATORS: 5-4400 KVA. 12000 VOLT 3 PHASE, 25 CYCLES, 5-4400 KVA. 2200 VOLT 2 PHASE 25 CYCLES
NET HEAD: 135 FT. UNIT EFFICIENCY: 78 % SHAFT: TUBULAR 3'-2" DIAM. PENSTOCKS: PLATE STEEL 7'-6" DIAM, 144 FT. LONG, SLIDING STEEL HEAD GATES. WATER SUPPLY: INTAKE CANAL ABOUT ONE AND A QUARTER MILES ABOVE FALLS, WIDTH 119 FT. TO 194 FT. AVERAGE DEPTH 12 FT., 1200 FT. LONG. SUPPLIES POWER HOUSE No 2 ALSO. DISCHARGE TUNNEL: HORSESHOE SHAPE, BRICK LINED, 21 FT. HIGH BY 18'-10" WIDE, 7481 FT. LONG. SAME TUNNEL DISCHARGES WATER FROM POWER HOUSE No. 2.
POWER HOUSE No. 2
CONSTRUCTED: 1900 TO 1904 INSTALLATION: 11-5000 H.P. UNITS, 250 R.P.M. TOTAL 55000 H.P. TURBINES: VERTICAL SHAFT, SINGLE RUNNER, FRANCIS TYPE, CYLINDRICAL GATES. GENERATORS: 11-4400 Kva. 2200 VOLT 2 PHASE 25 CYCLES NET HEAD: 135 FT. UNIT EFFICIENCY: 73 %
SHAFT: TUBULAR 3'-2" DIAM. PENSTOCKS: PLATE STEEL 7'-6" DIAM, 148 FT. LONG, SLIDING STEEL HEAD GATES. WATER SUPPLY AND DISCHARGE TUNNEL SAME AS POWER HOUSE No. 1

FIG. 6.

After much consideration a new type of plant was designed for the Edward Dean Adams Station. In this the water-wheels were placed in the bottom of a wheel-pit, about 24 ft. wide and 130 ft. deep, excavated in the solid rock. The discharge from the wheels was carried to the river through a flow-line tunnel about 7 000 ft. long, which discharged into the Gorge about ½ mile below the Falls. Long vertical shafts connected the water-wheels to the generators which were placed in a power house above ground.

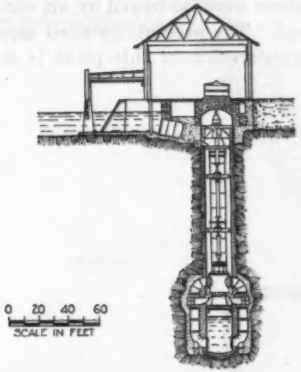
By 1895, alternating-current electrical power was being generated in Station No. 1 and delivered in Niagara Falls. Power was sent to Tonawanda,

N. Y., and Buffalo in 1896 by means of 11 000-volt transmission. By 1900, Station No. 1 had been completed with ten units of 5 000 h.p. each, and, by 1904, Station No. 2 had been completed with a further installation of eleven units of 5 000 h.p. each. Fig. 6 shows a typical cross-section of both stations. On the completion of Section C of the Schoellkopf Station in 1924, the twenty-one units aggregating 105 000 h.p. in the Adams Station were placed in reserve.

One of the questions most frequently asked is, "What led to the adoption of twenty-five cycles as the standard frequency of alternating current generated at Niagara Falls?" This question is answered by Mr. B. G. Lamme,[3] as follows:

"A speed of 250 revolutions per minute was decided upon. The engineers of the power company proposed eight-pole machines, giving 2 000 alternations per minute or 16⅔ cycles per second. The Westinghouse Company proposed, as an alternative, 16 poles giving 33⅓ cycles, the advantage claimed for this frequency being that it was better suited for motors and rotary converters, which were then promised to become of importance. One advantage claimed for the 16⅔-cycle machine was that it would permit the use of commutator type alternating-current motors. After much discussion, and weighing and balancing of all the various arguments for and against these two frequencies, it was finally decided to use 12 poles, giving 3 000 alternations per minute, or 25-cycle polyphase current, and as far as the writer knows, this was the origin of the present 25-cycle standard."

This station is named in honor of Edward Dean Adams, F. Am. Soc. C. E., who took a foremost part in the promotion of the undertaking and has been actively associated with The Niagara Falls Power Company since its inception.

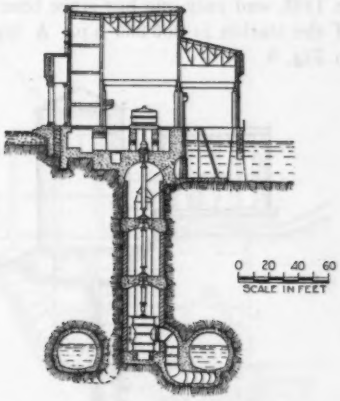


*William B. Rankine Station.*—About 1900, when the Edward Dean Adams Station No. 1 was nearing completion, the management of The Niagara Falls Power Company turned its attention toward the development of power on the Canadian side of the river, for which it had obtained rights from the Government of the Province of Ontario in 1892. By this time sufficient experience had been gained to warrant the construction of hydro-electric generating units of 10 000 h.p. capacity. The wheel-pit and tail-race tunnel type of plant was again adopted in the design of this station (Fig. 7). By 1905, power was being delivered from this Canadian plant and, by 1917, ten units had been installed having an aggregate capacity of 109 000 h.p. In 1924, Unit No. 11, of 12 000 h.p. capacity, was added, thus bringing the total installed capacity of the station up to 121 000 h.p.

This station is named in honor of William B. Rankine, who perhaps more than any other person bore the burden of the pioneer work in The Niagara Falls Power Company.

*International Railway Company.*—A small installation on the Canadian side of the river, a short distance above the Horseshoe Falls, was begun in 1892 and completed with a total installation of 3 600 h.p. in 1905. This plant is owned by the International Railway Company and is used to generate direct current for the operation of the railway.

[3] "Electrical Engineering Papers," p. 602.



*Toronto Power Company.*—Power projects at Niagara Falls began to multiply early in the Twentieth Century and two more plants were constructed on the Canadian side of the river. One of these was developed by the Electrical Development Company, now commonly referred to as the Toronto Power Company, a confusion which originated by substituting the name of the transmission company for that of the developing company. This Company followed somewhat the same lines of development as were used for the Adams and Rankine Stations, but brought the discharge end of its tail-race tunnel through the cliff directly behind the sheet of water falling over the Horseshoe Falls.

THE NIAGARA FALLS POWER COMPANY
WILLIAM BIRCH RANKINE STATION

CONSTRUCTED: 1901 TO 1924. INSTALLATION: 5 UNITS 10250 H.P., 2-12750 H.P., 3-10750 H.P., 42000 H.P., 250 R.P.M., TOTAL 11 UNITS 121000 H.P. TURBINES: VERTICAL SHAFT, FRANCIS TYPE, 7 DOUBLE RUNNER AND 4 SINGLE RUNNER, CYLINDRICAL GATES IN ALL BUT 12000 H.P. UNIT WHICH HAS WICKET GATES. GENERATORS: 5-8500 KVA., 5-10400 KVA., 1-11440 KVA., 12000 VOLT, 3 PHASE, 25 CYCLES. NET HEAD: 135 FT. UNIT EFFICIENCY: 70%. SHAFT: TUBULAR 3'-3½" DIAM. PENSTOCKS: PLATE STEEL 10'-2½" DIAM., 136 FT. LONG, SLIDING STEEL HEAD GATES. WATER SUPPLY: INTAKE CANAL ABOUT ONE QUARTER MILE ABOVE FALLS, 282 FT. TO 346 FT. WIDE, AVERAGE DEPTH 14'-6", LENGTH 300 FT. DISCHARGE TUNNEL: HORSESHOE SHAPE, BRICK LINED, 25 FT. HIGH BY 18'-10" WIDE, 2165 FT. LONG.

FIG. 7.

THE TORONTO POWER COMPANY

CONSTRUCTED: 1903 TO 1915. INSTALLATION: 7 15000 H.P. UNITS, 4 13000 H.P. UNITS, 250 R.P.M. TOTAL 11 UNITS 157000 H.P. TURBINES: VERTICAL SHAFT, DOUBLE RUNNER, FRANCIS TYPE, 250 R.P.M. GENERATORS: 7-10000 KVA., 4-8000 KVA., 12000 VOLTS, 3 PHASE, 25 CYCLES. NET HEAD: 135 FT. SHAFT: TUBULAR 2'-6" DIAM. PENSTOCKS: PLATE STEEL 10'-6" DIAM. 145 FT. LONG, SLIDING STEEL HEAD GATE. WATER SUPPLY: INTAKE AND POWER HOUSE ABOUT ONE HALF MILE ABOVE FALLS. DISCHARGE TUNNEL: 2 BRANCH TUNNELS 25 FT. HIGH AND 16 FT. TO 28'-9" WIDE, ABOUT 500 FT. LONG UNITE AND FORM MAIN HORSESHOE SHAPE TUNNEL 26 FT. HIGH BY 23.5 FT. WIDE, 1935 FT. LONG, BRICK LINED.

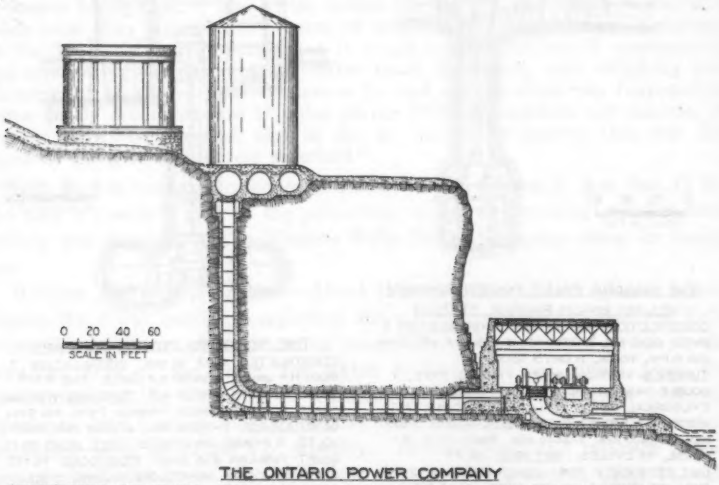


FIG. 8.

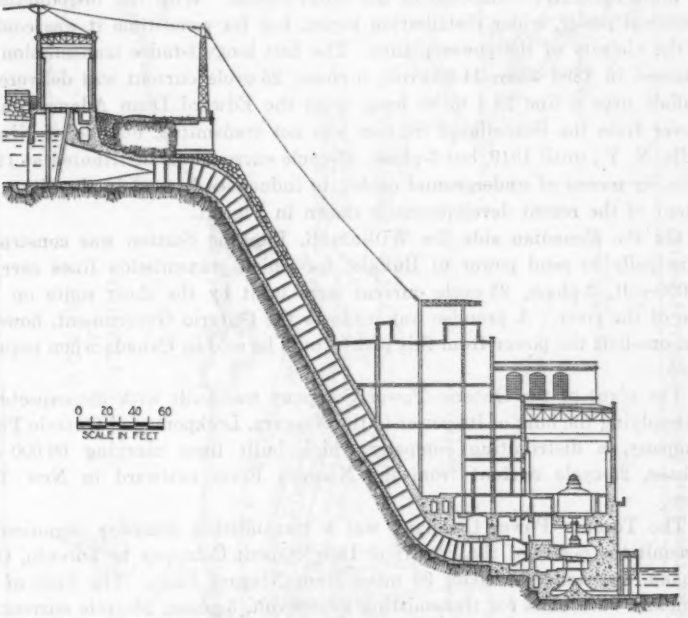
The station was first put into operation in 1906, and was completed by 1915. There are four units of about 13 000 h.p. capacity each, and seven of 15 000 h.p. each, making up a total of 157 000 h.p. for the station. A typical cross-section is shown in Fig. 8. The plant was sold to the Hydro-Electric Power Commission of Ontario in 1918.

*Ontario Power Company of Niagara Falls.*—The other Company to begin work early in the Twentieth Century was the Ontario Power Company. This Company departed from the types of plant previously built and used pressure

conduits about 6 000 ft. long to carry water taken from the river above the Upper Rapids to penstocks connected to water turbines located in a power house in the Gorge just below the Horseshoe Falls.

Power from this plant was first produced in 1905. By 1913, two main conduits, one of plate steel and one of reinforced concrete, each having an internal diameter of 18 ft., and a power house containing fourteen units with a total installed capacity of 186 050 h.p., had been completed. In 1917 this Company was purchased by the Hydro-Electric Power Commission of Ontario. In 1918, as a World War measure, a third conduit, 13½ ft. in diameter, was constructed of wood and used to supply two additional units aggregating 36 000 h.p. capacity. Both of these were destroyed by an accident in 1923, and only one has since been restored. The present installed capacity of the station is 205 350 h.p. A typical cross-section of this plant is shown in Fig. 9.



THE ONTARIO POWER COMPANY

CONSTRUCTED: 1902 TO 1923. INSTALLATION: 3-12350 H.P UNITS, 4-13250 H.P UNITS, 4-13500 H.P. UNITS, 3-14000 H.P. UNITS, AND 1-19300 H.P. UNIT. 187½ R.P.M. TOTAL 15 UNITS 205350 H.P. TURBINES: HORIZONTAL SHAFT, 2 TURBINES ON SHAFT, FRANCIS TYPE, SCROLL CASE, WICKET GATES. GENERATORS: 3-7500 KVA., 4-8773 KVA., 7-8776 KVA., 1-15000 KVA., 12000 VOLTS, 3 PHASE, 25 CYCLES. NET HEAD: 180 FT. PENSTOCKS: PLATE STEEL VARYING FROM 225 FT TO 307 FT LONG, 14-9'0" DIAM. AND 1-10'6" DIAM., GATE VALVES 12 UNITS AND JOHNSON VALVES 3 UNITS. WATER SUPPLY: INTAKE ABOUT THREE QUARTERS OF A MILE ABOVE FALLS. 3 PIPE LINES, 1 PLATE STEEL, 6300 FT. LONG, 18'-0" DIAM., 1 REINFORCED CONCRETE, 6500 FT. LONG, 18'-0" DIAM., 1 WOOD STAVE, 6700 FT LONG, 13'-6" DIAM. SIMPLE OVERFLOW CHAMBER AT END OF STEEL PIPE LINE AND DIFFERENTIAL SURGE TANKS AT END OF CONCRETE AND WOOD STAVE PIPE LINES.

FIG. 9.

*Queenston-Chippawa Development.*—The latest power plant built at Niagara Falls was constructed on the Canadian side during the years 1917 to 1921, by the Hydro-Electric Power Commission of Ontario. This plant takes its water from the Niagara River through an intake at the mouth of the Welland River and by reversing the natural flow for a distance of 4½ miles the water is delivered to a canal, 48 ft. wide and about 30 ft. deep, below the

water-line. The canal was excavated in earth and solid rock for a distance of 8 miles to a point on the Gorge of the Lower Niagara River about 2 miles above the Village of Queenston, Ont., Canada.

THE HYDRO-ELECTRIC POWER COMMISSION OF ONTARIO

QUEENSTON - CHIPPAWA DEVELOPMENT

CONSTRUCTED: 1917 TO 1925. INSTALLATION: 5-55000 H.P. UNITS AND 4-58000 H.P. UNITS, 187.5 R.P.M., TOTAL 9 UNITS 507000 H.P. TURBINES: VERTICAL SHAFT, SINGLE RUNNER, FRANCIS TYPE, SCROLL CASE. GENERATORS: 5-45000 KVA., 4-55000 KVA., 12000 VOLTS, 3 PHASE, 25 CYCLES. NET HEAD: 305 FT. PENSTOCKS: 437 FT. LONG, 65 FT. OF UPPER HORIZONTAL SECTION SOLID ROCK CONCRETE LINED, 372 FT. PLATE STEEL ENCASED IN CONCRETE, 5 ARE 16'-0" DIAM. FOR ABOUT 2/3 THEIR LENGTH AND THEN REDUCE TO 14'-0" DIAM., AND 4 ARE 16'-0 DIAM. THROUGHOUT, SLIDING STEEL HEAD GATES. JOHNSON VALVES: 14'-0" INLET DIAM., 10'-0" OUTLET DIAM. WATER SUPPLY: INTAKE FROM NIAGARA RIVER AT MOUTH OF WELLAND RIVER, FLOW IN WHICH IS REVERSED FOR A DISTANCE OF 4 1/2 MILES TO CANAL ENTRANCE. CANAL 8 MILES LONG. EXCAVATION IN EARTH AND SOLID ROCK. ROCK SECTION 48 FT. WIDE, 30 FT. DEEP, CONCRETE LINED.

FIG. 10.

The gross head from intake to tail-water is 312 ft. Operation was commenced in December, 1921, and, by 1925, the ninth and last unit was completed. The first five units have capacities of 55 000 h.p. each, and the last four are 58 000 h.p. each, making the total installed capacity 507 000 h.p. A typical cross-section of the generating station is shown in Fig. 10.

## Transmission and Distribution

It will naturally be asked, "Where and how has Niagara power been used?" Of course, in the early stages of development, all the power was used locally in mills by drives connected to the water-wheels. With the introduction of electrical power, wider distribution began, but for some time it was confined to the vicinity of the power plants. The first long-distance transmission was attained in 1896 when 11 000-volt, 3-phase, 25-cycle current was delivered in Buffalo over a line 22.4 miles long, from the Edward Dean Adams Station. Power from the Schoellkopf Station was not transmitted outside of Niagara Falls, N. Y., until 1919, but 3-phase, 25-cycle current was distributed at 12 000 volts, by means of underground cables, to industries located in the city. The extent of the recent development is shown in Fig. 11.

On the Canadian side the William B. Rankine Station was constructed principally to send power to Buffalo, for which transmission lines carrying 22 000-volt, 3-phase, 25-cycle current were built by the short route on that side of the river. A promise was made to the Ontario Government, however, that one-half the power from this plant would be sold in Canada when required there.

The plant of the Ontario Power Company was built with the expectation of supplying the bulk of its power to the Niagara, Lockport, and Ontario Power Company, a distributing company which built lines carrying 60 000-volt, 3-phase, 25-cycle current from the Niagara River eastward in New York State.

The Toronto Power Company was a transmission company organized to transmit the power of the Electrical Development Company to Toronto, Ont., Canada, a distance of about 90 miles from Niagara Falls. The lines of the Company were built for transmitting 60 000-volt, 3-phase, 25-cycle current.

About 1903, a number of municipalities in Western Ontario, noting that no plans had yet been made to send Niagara power to them, and apprehensive lest they might be left in the lurch, petitioned the Government of the Province for permission to form an organization to purchase power from the generating companies at Niagara Falls and transmit it to their municipalities. As a result the Hydro-Electric Power Commission of Ontario was created in 1905, which contracted for the supply of 100 000 h.p. from the Ontario Power Company and built transmission lines to distribute this power throughout the southwestern end of the Province. This system was built for transmitting 110 000-volt, 3-phase, 25-cycle current.

From such beginnings the present distribution (Fig. 11) was gradually developed until now (1928), by purchases and consolidations, the generation and transmission of Niagara power throughout the western part of the State of New York and the southwestern part of the Province of Ontario are largely concentrated in two large systems. One of these serves a population of more than 2 500 000 in the State of New York (and in a small part of the Province of Ontario). The territory involved has an area of 14 500 sq. miles extending to the east as far as Altmar, N. Y., a distance of 200 miles, and to the south, 100 miles to the border of the State of Pennsylvania.

FIG. 11.—MAP OF TERRITORIES SERVED BY NIAGARA POWER.

In the Province of Ontario, the other system serves a population of about 1 500 000, occupying 13 500 sq. miles. This territory extends 225 miles to Windsor on the west and 90 miles around the west end of Lake Ontario to Toronto, and north therefrom a distance of 50 miles to Sutton.

The American and Canadian lines are interconnected at Niagara Falls. These, in turn, are interconnected with other systems, the American lines in New York State being connected to those of the Northern New York Utilities, Rochester Gas and Electric Company, Syracuse Lighting Company, and the Mohawk Hudson Power Corporation. The Canadian lines in the Province of Ontario are connected with the Georgian Bay System of the Hydro-Electric Commission.

In 1927 the generating stations at Niagara Falls produced 6 772 944 200 kw-hr. The maximum peak load produced by the American plant was 365 659 kw., and by the Canadian plants, 694 000 kw.

### Limitation of Diversion of Water

About 1906, when several power developments were under construction on the Canadian side and in contemplation on both sides, an agitation was begun in the United States to preserve the scenery of Niagara Falls. Fears were expressed that soon power plants and factories would line the banks of the river and all the water would be diverted from the cataracts to drive hydraulic turbines, leaving only ugly, bare rock cliffs standing in place of the grandeur of the Falls. It seemed easier to remedy the evil by prohibition rather than by suitable correction.

*The International Waterways Commission.*—"The Rivers and Harbors Act", passed by the United States Congress and approved June 13, 1902, contained a provision authorizing the President to request the Government of Great Britain to join in the formation of the International Waterways Commission. A Commission was thus appointed to investigate and report on the conditions and uses of the waters adjacent to the boundary lines between the United States and Canada. The first meeting was held in Washington, D. C., on May 25, 1905, and the second in Toronto on July 14 and 15, 1905. At the latter meeting the Commission considered the question of using the waters of the Niagara for power purposes and the regulations necessary to insure equitable division of the waters between the two countries and the protection of Niagara Falls as a scenic spectacle.

On October 28, 1905, the Commission passed a resolution recommending to the Governments of the United States and Canada that steps be taken to prevent any corporate rights and franchises being granted or renewed by either Federal, State, or Provincial authority for the uses of the waters of the Niagara River for power or other purposes until the Commission was able to collect information necessary to enable it to report fully on the condition and uses of those waters.

*The Burton Bill.*—On June 29, 1906, an Act of Congress was approved prohibiting all diversion for power purposes on the American side without the consent of the Secretary of War, and limiting the diversions which, in any event, could be permitted to 15 000 cu. ft. per sec. This bill remained in force

for three years. It was renewed for two years from June 29, 1909, and after two other extensions it lapsed March 4, 1913.

*The International Boundary Waters Treaty of 1910.*—Pursuant to the terms of the Burton Act and following the investigations of the Waterways Commission, a treaty between the United States and Great Britain was ratified in 1910 and is now known as the Boundary Waters Treaty.

Among its provisions, the following clauses are of special interest:

"The High Contracting Parties shall have each on its own side of the boundary equal and similar rights in the use of the waters hereinbefore defined as boundary waters."

* * * * * *

"The requirements for an equal division may in the discretion of the Commission, be suspended in cases of temporary diversions along boundary waters at points where such equal division cannot be made advantageously on account of local conditions and where such diversion does not diminish elsewhere the amount available for use on the other side."

* * * * * *

"The High Contracting Parties agree that it is expedient to limit the diversion of waters from the Niagara River so that the level of Lake Erie and the flow of the stream shall not be appreciably affected. It is the desire of both Parties to accomplish this object with the least possible injury to investments which have already been made in the construction of power plants on the United States side of the river under grants of authority from the State of New York, and on the Canadian side of the river under licenses authorized by the Dominion of Canada and the Province of Ontario.

"So long as this treaty shall remain in force no diversion of the waters of the Niagara River above the Falls from the natural course and stream thereof shall be permitted except for the purposes and to the extent hereinafter provided.

"The United States may authorize and permit the diversion within the State of New York of the waters of said river above the Falls of Niagara, for power purposes, not exceeding in the aggregate a daily diversion at the rate of twenty thousand cubic feet of water per second.

"The United Kingdom, by the Dominion of Canada, or the Province of Ontario, may authorize and permit the diversion within the Province of Ontario of the waters of said river above the Falls of Niagara, for power purposes, not exceeding in the aggregate a daily diversion at the rate of thirty-six thousand cubic feet of water per second.

"The prohibition of this article shall not apply to the diversion of water for sanitary or domestic purposes, or for the service of canals for the purpose of navigation."

In view of the first clause quoted, it is interesting to inquire what possible reasons led to the inequality in the diversions permitted at Niagara Falls. The treaty itself gives no specific reason for allowing 36 000 cu. ft. per sec. to Canada and 20 000 cu. ft. per sec. to the United States, beyond stating that it is the desire of both parties to accomplish the object of the treaty with the least possible injury to investments which had already been made in the construction of power plants.

It is probable that there were at least four factors which led to the unequal division:

1.—The desire to impose limitations on the total diversions without injury to investments already made.

2.—The equalizing effect of generating power on the Canadian side and transmitting it to the United States.

3.—The position of two of the plants on the Canadian side, with intakes below the crest of the upper cascades and, therefore, not affecting the American Falls.

4.—The works constructed at Chicago, Ill., for the diversion of water from the Great Lakes.

The limitation of diversion of water imposed by the treaty restricts the aggregate output of the power plants at Niagara Falls to an amount considerably below their combined installed capacities. It is for this reason that the Edward Dean Adams Plant is held in reserve as previously stated.

Table 1 shows power statistics for the various plants when operated in accordance with the provisions of the treaty.

TABLE 1.—Limits of Operation, Niagara Power Plants.

| Plant. | Installed capacity, in horse-power. | Present Use Under Treaty Limitations. | |
|---|---|---|---|
| | | Average horse-power. | Peak horse-power. |
| Schoellkopf | 452 500 | 417 000 | 488 000 |
| Edward Dean Adams | 105 000 | 0 | 0 |
| William B. Rankine | 121 000 | 100 000 | 100 000 |
| International Railway Company | 3 600 | ..... | ..... |
| Ontario Power Company | 205 350 | 130 000 | 180 000 |
| Toronto Power Company | 157 000 | 20 000 | 100 000 |
| Queenston-Chippawa | 507 000 | 470 000 | 520 000 |
| Total | 1 551 450 | 1 137 000 | 1 388 000 |

## Effect of Power Development on Lake Erie and the Niagara River

*Relation Between Lake Erie Stage and Niagara Discharge.*—The equation relating the discharge of the Niagara River to the stage of Lake Erie has been determined by the engineers of the United States Government as follows:

$$Q = 3\,904\,(H - 558.37)^{\frac{3}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which,

$Q$ = discharge of the river, in cubic feet per second; and,

$H$ = elevation above mean sea level of the surface of the water in the lake, Buffalo Gauge.

The mean value of $H$ for the period, 1860 to 1927, inclusive, was 572.50.

Considering the relation of Equation (1) roughly, it may be stated that, when the stage of Lake Erie has risen 1 ft. above this mean level, there will be an increase of about 22 400 cu. ft. per sec. in the rate of discharge of the Niagara River; and, when the stage of the lake has fallen 1 ft. below its mean level, there will be a corresponding reduction in discharge of about 21 600 cu. ft. per sec.

*Variations in Lake Levels and Discharge.*—There are three kinds of variations in lake level and discharge of the Niagara River:

(1) Seasonal variations every year.
(2) Cycles of change due to variable supply from precipitation and run-off.
(3) Daily fluctuations on account of the changes in atmospheric pressure and in the direction and velocity of winds.

A study of the records of the monthly mean lake levels and discharges of the Niagara River will show that the normal seasonal variation in lake level is about 1.5 ft., and that the normal seasonal variation in discharge of the Niagara River is about 31 900 cu. ft. per sec.

In addition to the seasonal variations there are periodic fluctuations in lake level and corresponding variations in river discharge extending over a period varying from seven to eleven years, the effect of which is to make the difference between the maximum mean monthly level of Lake Erie and its minimum mean monthly level about 5.0 ft. These variations correspond to a difference between the maximum and the minimum discharges of the Niagara River of about 107 900 cu. ft. per sec.

Changes in the direction and velocity of winds on Lake Erie and in atmospheric pressure produce greater fluctuations, than the foregoing and independent of them, but only for periods of short duration. The difference between the maximum and the minimum level of the lake from this cause is about 13.0 ft. Table 2 shows the ranges in level and the corresponding discharges for the period, 1860 to 1927, inclusive.

TABLE 2.—VARIATIONS OF LEVEL IN LAKE ERIE AT BUFFALO, N. Y., AND OF DISCHARGE OF THE NIAGARA RIVER.

| | Elevation, in feet. | Discharge, in cubic feet per second. |
|---|---|---|
| Average monthly mean (1860-1927 inclusive) | 572.50 | 207 400 |
| Average maximum monthly mean | 573.18 | 222 500 |
| Average minimum monthly mean | 571.73 | 190 600 |
| Maximum monthly mean (June, 1876) | 574.68 | 257 200 |
| Minimum monthly mean (February, 1926) | 569.72 | 149 300 |
| Maximum lake level due to wind | 580.28 | ..... |
| Minimum lake level due to wind | 567.38 | ..... |

*Effect of Diversions.*—It is claimed that the navigable depths of Lake Erie have been rendered insufficient from various causes, such as:

(1) Deficient precipitation and run-off.
(2) Diversions of water from the Great Lakes through:
*a.*—Chicago Drainage Canal
*b.*—Welland Canal
*c.*—Black Rock Ship Canal
*d.*—New York State Barge Canal
*e.*—Power plants at Niagara Falls.

Prior to 1927, the most authoritative estimate of the amount of the lowering at mean stage caused by all these diversions was 0.76 ft.[4] Of this total,

[4] Report on the Diversion of Water from the Great Lakes and Niagara River, by J. G. Warren, M. Am. Soc. C. E., p. 375.

the amount of lowering caused by diversions for power purposes at Niagara Falls was considered to be 0.1 ft., at least one-half of which had been compensated for by changes in the bed of the river. The amount of this lowering has been placed by other estimates as high as 3½ in.

Actually, however, measurements made in the Niagara River during the summer of 1925, under the direction of the District Engineer Office, at Buffalo, indicate that there has been no appreciable change in the relation between the discharge of the river and the stage of Lake Erie since 1900 when measurements were made by the U. S. Lake Survey Office under the direction of Francis C. Shenehon, M. Am. Soc. C. E. Such differences as were found between the measurements of 1925 and 1900 were in the opposite direction, indicating that the level of Lake Erie for a given discharge of the Niagara River had become slightly higher than in 1900. This is due probably to compensatory changes in the shore line and bed of the river, which have offset any effects that otherwise might have been caused by diversion.

Back-water studies of the flow of the Niagara River indicate that it would require a lowering of approximately 2.0 ft. in the river level at Port Day to cause a decrease in the level of Lake Erie by as much as 3.5 in. No such lowering at Port Day has occurred.

*Proposed Regulation.*—It has been proposed from time to time to hold Lake Erie, as well as the other Great Lakes, as nearly as possible at a uniform elevation, in order that the navigable depth will not be lessened during the low-water season each year, particularly in years of low levels following periods of deficient natural supply. For this purpose various means have been suggested, such, for instance, as a regulating dam with gates and sluices at the outlet of Lake Erie, or across the Niagara River between Port Day and Chippawa, Ont., Canada. In operating such a dam it is proposed to raise or lower the gates so as to control the outflow from the lake, allowing more water to flow out when the lake is rising and less when it is falling. It is not usually expected by this means to hold it at a uniform level, but merely to restrict the range of variation to something less than when it is left free under natural conditions.

Evidently the monthly mean level of the lake cannot be kept more nearly uniform without at the same time causing more variation in the monthly mean flow of the Niagara River, assuming that the supply to the lake will vary from natural causes as in the past. In periods of deficient supply a part of the flow of the river comes from the water stored in the lake, thereby causing lake levels to fall; and in periods of excess supply the water cannot flow through the river as fast as it enters the lake, thus causing lake levels to rise.

If Lake Erie is to be regulated in such a way that the difference between the maximum and the minimum mean monthly water level will be less than in the past, the effective storage capacity of the lake will be reduced. Then the difference between the volumes of water discharged in the Niagara River at rates higher and lower than the mean must necessarily be greater than in the past. Conversely, if the flow of the river is to be made more nearly uniform, a greater storage capacity will be required; and, consequently, the difference between the maximum and the minimum level of Lake Erie must be greater than it has been in the past. If it is desired to increase the depth

of Lake Erie for navigation purposes and, at the same time, to obtain greater regularity of flow in the Niagara River, it would be necessary to provide regulating works which will have the effect of raising the mean level of the lake to a higher plane. The necessary fluctuations in lake level would then occur above and below this plane to the extent necessary to maintain the greatest possible degree of regularity in the flow of the river.

The area of Lake Erie is approximately 10 000 sq. miles. When its level is lowered 1 ft. below the mean, a volume of water is supplied to the Niagara River sufficient to maintain its entire average flow for about sixteen days. If the flow of the river were completely shut off for one day, the use of the water for power and scenic purposes would cease, but the level of the lake would be raised only about 0.75 in. It is thus apparent that obstructions which tend to interfere temporarily with the flow of the river are of much greater significance in respect to variation in flow than to water level in the lake.

*Proposed Regulation and Compensation Works.*—Regulating works and compensating works for Lake Erie have been proposed from time to time since about 1900. The object of regulating works is to control the outflow so as to increase the navigable depths during otherwise naturally low-water periods.

Compensating works are different in that they are designed only to raise the mean level of the lake without attempting to control the natural variations. Fluctuations will occur above and below a certain plane higher than that existing before the works were constructed; but the depths at all stages will be greater.

*Location of Proposed Regulating Works.*—It has been proposed that such works be located either at the entrance to the Niagara River, near the outlet of Lake Erie, or in the river, between Port Day and Chippawa. If the value of lake regulation is sufficient to offset the economic loss of the present natural conservation of water supply for power purposes in the Niagara and St. Lawrence Rivers, the former location is preferable.

A regulating dam between Port Day and Chippawa just above the Falls, would offer serious difficulties from the standpoint of power development. No structure must be placed in the Niagara River which will endanger the supply of water to the power plants by interfering with the passage of the large volumes of ice each winter. The height to which the water would have to be raised at Port Day to produce an appreciable effect on the levels of Lake Erie would be so great that important additions would have to be made to the power plants.

Lands lying along the river above Niagara Falls and along the tributary creeks, would have to be protected and drained. The sewage of La Salle, Tonawanda, and North Tonawanda, N. Y., would have to be cared for. A guard-lock would have to be constructed at the entrance to the Barge Canal at Tonawanda; and it is probable that the Buffalo Breakwater and the dike forming the Black Rock Ship Canal would have to be modified.

Referring now to the economic loss of power incurred by regulating Lake Erie so that its variation in level will be less than in the past, it will

be assumed that the usable flow of the river will be some function of the "50% time flow" referred to by the Advisory Committee of the International Electrotechnical Commission of Rating of Rivers. It will be noted that the 50% time flow of the Niagara River may be utilized with an average load factor as high as 96 per cent.

One proposed rule of regulation may be applied to the measured discharge of the Niagara River during the period 1860 to 1924, inclusive, on the assumption that the minimum flow of the Niagara River would not be permitted to be less than 180 000 cu. ft. per sec. Then to obtain a regulation of mean monthly levels of Lake Erie within a range of 1.5 ft. and to provide for a diversion of 13 000 cu. ft. per sec. from and above the lake for navigation and other purposes, it would be necessary to maintain the regulated minimum flow of 180 000 cu. ft. per sec. approximately 68% of the time.

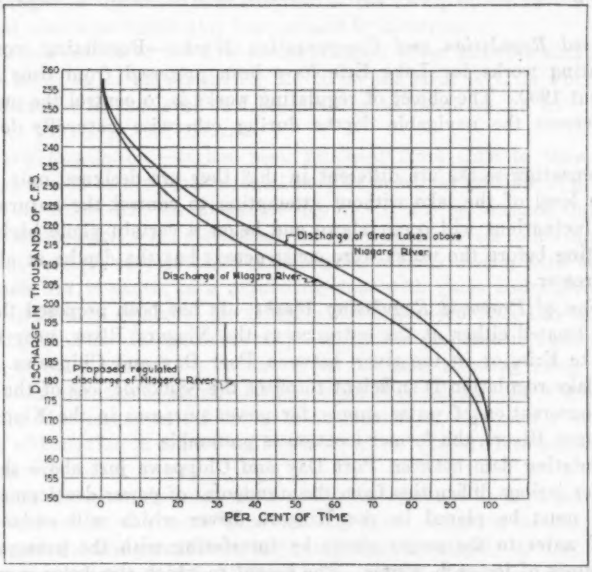


FIG. 12.—DURATION CURVE OF NIAGARA POWER, PERIOD 1864 TO 1902, INCLUSIVE.

Under natural conditions during this period the 50% time flow from the Great Lakes above the Niagara River was approximately 214 500 cu. ft. per sec. and for 3½% of the time the flow was less than 180 000 cu. ft. per sec.

Integrating under the natural and regulated duration curves (Fig. 12), it will be found that the volume of usable water added to the natural low flows by the regulation of the minimum to 180 000 cu. ft. per sec. is about 1.8% of the volume of usable water lost from the natural 50% time flow. The net loss to power development on the Niagara River is, therefore, nearly 2 000 000 000 kw-hr. per year. To this would have to be added also the loss of power on the St. Lawrence River.

The value of this power must be considered as a charge against the benefits to be derived from regulated navigable depths and from the use of water diverted for other purposes. This conclusion is not altered by reason of the fact that part of the flow of the Niagara River is required for scenic purposes, because such water, which has been fixed by some authorities at 80 000 cu. ft. per sec., is considered to be the first claim on the river, and what remains is to be available for power purposes. The difference between the usable quantities indicated is not altered, therefore, by any such fixed allowance for scenic purposes.

## Economic Benefits of Niagara Power

The question of the value of Niagara power to the districts which it serves is especially important because so much is being said about the remarkable and undeniable accomplishments in the field of steam-electric generation. It would be a mistake, however, to assume that recent great improvements in the economy of steam generation, forming as they do one of the brightest chapters in the record of the Engineering Profession, have yet reached the point, or are indeed likely to reach that point, where all water power may be thrown into the discard.

Comparisons of the cost of electric service in widely separated areas of the Continent, while of considerable interest, are perhaps of doubtful significance because charges for such service are so largely dependent on economic conditions in the localities where the service is rendered. Rates for electric light and power depend primarily on the capital costs of the generating, transmitting, and distributing systems, and on the number of kilowatt-hours which can be sold per dollar of capital invested. The former, in turn, depend on the physical conditions affecting the construction of the systems and on the costs of labor and materials, and the value of land. The kilowatt-hours, on the other hand, depend on the density of population and the value to the user of the service rendered. Taxes and the amounts reserved for plant renewals are important items of annual expense in addition to labor cost and interest on the invested capital.

There is a tendency to assume in public discussions of electric rates, that electricity as a commodity differs from nearly every other one in the world, in that it can be sold for the same price no matter where or under what conditions it is produced. It is also frequently assumed that electric service is a monopoly requiring something more than the ordinary economic laws to regulate its price.

Protection of the public interest by regulatory commissions does not alter the fact that in many ways the electrical business is highly competitive. Electricity competes with gas, oil, and other fuels in the same district. One district competes with another for the growth of business, and some industries largely dependent on electricity compete with like industries over the entire world. More especially, perhaps, electricity competes with all other commodities, such as motor cars, radios, etc., for its share of the consumer's dollar. Such competition effectively tends to regulate prices of electric service to their minimum economic level.

TABLE 3.—NIAGARA POWER—COST AND CAPACITY, INCLUDING AUXILIARY PLANTS, 1926.

| Territory. | Fixed electrical capital. | Installed capacity, in kilowatts. | Capital per kilowatt. |
|---|---|---|---|
| Western New York..... | $205 932 420 | 770 989 | $267 |
| Southwestern Ontario.. | $251 938 759 | 814 826 | $309 |

The data in Tables 3 and 4, taken mainly from published financial reports, are presented not to indicate that rates for electricity in some other district should be different from what they are, but merely to show how the large territories served by Niagara power have benefited by the utilization of a small part of the energy made available by this great gift of Nature. Later, it will be indicated how further developments may be made without materially sacrificing those æsthetic benefits which are to be derived by the contemplation of the scenery of the Falls.

TABLE 4.—NIAGARA POWER—REVENUES, 1926.

| Territory. | Electrical operating revenue from sale of electrical energy. | Electrical operating revenue from sale of electrical energy (taxes deducted). | Total kilowatt-hours generated or purchased. | REVENUE, IN MILLS PER KILOWATT-HOUR. | |
|---|---|---|---|---|---|
| | | | | Taxes included. | Taxes deducted. |
| Western New York.... | $41 558 864 | $36 531 624 | 4 495 959 612 | 9.24 | 8.13 |
| Southwestern Ontario. | 26 093 911 | 25 804 658 | 2 821 791 607 | 9.25 | 9.14 |

The average revenue received per kilowatt-hour from the sale of power in other territories less favorably situated and served largely by steam, is from two and one-half to three times as great. These statistics prove conclusively, therefore, that the economic benefits of Niagara power have been passed on to the users. They disprove the assumption, frequently made, that the difference between the cost of water power and steam power is collected from the consumer and retained wholly for the benefit of the shareholders of the companies undertaking the development.

## ULTIMATE DEVELOPMENT OF NIAGARA FALLS

Preservation of their scenic grandeur is the most important factor involved in the ultimate development of the Falls of Niagara. The discussion of this subject would be quite simple if it could be based on Lord Kelvin's prophecy, which, on the occasion of his visit to Niagara Falls in 1897, he expressed in these words:

"I look forward to the time when the whole water from Lake Erie will find its way to the lower level of Lake Ontario through machinery, doing more good for the world than even that great benefit which we now possess in contemplation of the splendid scene which we have before us in the waterfall of Niagara. I wish I could live to see this grand development. I do not hope that our children's children will ever see the Niagara cataract."

Under such conditions scenery would become a negligible factor, and power can be imagined as enthroned in two huge generating stations, extending half a mile along each side of the river at the foot of the Lower Rapids near Lewiston and Queenston, Ont. Giant generating units would produce 7 000 000 h. p. "on peak" and an average of about 6 000 000 h. p. daily throughout the year.

Such was the vision of Lord Kelvin thirty years ago. To-day, it is doubtful whether any one would venture to make such a prediction. On the contrary, for the past twenty years attention has been directed not only to the possibility of diverting more water for power purposes, but to showing how to preserve the scenery of the Falls and Rapids by providing works to remedy the effects of diversion and of the continued rapid recession of the crest of the Horseshoe Falls.

*Major Keller.*—Commencing with the report of Maj. Charles Keller, U. S. A. (now Colonel, U. S. A. (*Retired*)), M. Am. Soc. C. E., in 1908 on the preservation of Niagara Falls, a few quotations will be given. Major Keller states:

"In my opinion, the damage already done, and that which may be anticipated from further diversions and from the impending fall in the level of Lake Erie, may be largely, if not entirely, remedied by a submerged dam placed in the bed of the river immediately above the Horseshoe Falls."

*International Waterways Commission.*—About the same time the International Waterways Commission, in its joint report dated 1908, made the following recommendation with reference to diversions around the Lower Rapids:

"It is our opinion that about 40 000 cubic feet per second can be diverted without perceptible injury to the rapids, * * *."

*John L. Harper.*—Following these two recommendations, the late John L. Harper, M. Am. Soc. C. E., in 1918, published a pamphlet directing attention to the need for the preservation of scenic effects, stating:

"* * * it should be the policy of those controlling the falls at Niagara to have constructed in the bed of the river, above the Horseshoe Falls, invisible current deflectors which would make impossible the gathering of the whole river into a deep narrow gorge, and would again deflect its waters over the sides and heels of a re-established horseshoe * * * causing the whole contour of the fall to wear uniformly * * *."

*Colonel J. G. Warren.*—One year afterward, the well-known Warren report of Col. J. G. Warren, U. S. A. (*Retired*), M. Am. Soc. C. E., then Division Engineer at Buffalo, contained the following:

"If the remedial works * * * are provided, it is believed a total diversion of 80 000 cubic feet per second may be made around the Falls, and 40 000 around the Whirlpool and Lower Rapids without injury to the scenic beauty, and without endangering the ice-discharging capacity of the Falls or Rapids, these diversions to be divided equally between Canada and the United States."

*Board of Engineers for Rivers and Harbors.*—This report was then submitted to the Board of Engineers for Rivers and Harbors, headed by the late Maj. Gen. H. Taylor, U. S. A., (*Retired*), M. Am. Soc. C. E., which, in a

report dated August 24, 1920, approved the recommendations of the Division Engineer as to the necessity for remedial works, as follows:

"So far as concerns the preservation of scenic beauty, the most important measure suggested by the Division Engineer is the construction of a weir and certain rock excavation for the uniform distribution of flow over the Horseshoe, * * *. To preserve the flow of the American Fall he recommends a rough submerged weir between the head of Goat Island and the Canadian side, part of which has already been made by dumping dredge spoil.

"We are in accord with these recommendations of the Division Engineer as to the advantage of distributing as nearly uniformly as possible the water flowing over the Horseshoe Fall and as to the general method by which this can be accomplished."

* * * * * *

"No definite limit should be set upon the critical discharge over the Falls and the amount of water permitted to be diverted, other than to state that the remedial works should be designed so as to afford the maximum attainable scenic beauty, in our opinion corresponding to an ultimate diversion of 100 000 to 110 000 cubic feet per second."

*Special International Niagara Board.*—Finally, in 1926, the Governments of the United States and Canada appointed a Commission, known as the Special International Niagara Board, to study and report on the problem. Pending the preparation of its final report, the Board issued an interim report in December, 1927, which contains interesting recommendations covering the construction of initial remedial works at an estimated cost of $1 750 000, for the preservation of the scenic values of the Falls.

This report led to an agreement between the United States and Canada covering the construction of the remedial works recommended by the Board. The agreement was embodied in a Convention and Protocol signed in Ottawa, Ont., Canada, January 2, 1929, ratified by the Parliament of Canada, May 20, 1929, and, at present (June, 1929), is awaiting ratification by the Senate of the United States.

*Scenery and Power.*—Evidently, the ultimate development of the Falls of Niagara, for many years at least, will represent a compromise between the demands of scenery and of power. Lest it should be inferred that these are always opposed to one another, it may be noted that the requirements of power actually may be made to serve the needs of scenery. Furthermore, economic pressure surely will demand the same efficiency in the use of water for scenery as for power.

The maximum diversions officially recommended to date, however, are only 100 000 cu. ft. per sec. around the Falls and 40 000 cu. ft. per sec. around the Lower Rapids, provided suitable works are constructed for the preservation of the scenery and the regulation of the river.

*Existing Plants.*—The distribution of power and use of water in the existing plants is shown on Fig. 1. No attempt has been made to account for small quantities of treaty water, such as those used through the New York State Barge Canal and in the plant of the International Railway in Canada. Neither will the subsequent discussion be complicated by reference to the division of water between the United States and Canada. The principle of equality in respect of the use of boundary waters has already been agreed upon and ultimately the benefits of Niagara diversion will be divided equally between the two countries.

The notes on Fig. 1 show that, with the present allowed diversion of 56 000 cu. ft. per sec., a daily average output of 1 137 000 h.p. and a peak of about 1 388 000 h.p. are being produced. A ratio of 1 : 1.2 between average and peak for the plants on the American side has been fixed by the Federal Power Commission. No ratio has yet been fixed on the Canadian side.

An average of about 16 000 cu. ft. per sec. are being diverted around both the Falls and the Rapids. The remaining 40 000 cu. ft. per sec. are being diverted around the Falls only.

*Proposed New Plants.*—If new plants using a 312-ft. head are built to utilize the 24 000 cu. ft. per sec. remaining out of the 40 000 now recommended for diversion around the Falls and Rapids, the present plants (1928) are sufficient to utilize the remaining 60 000 cu. ft. per sec. around the Falls. Under these conditions, the ultimate development would give about 2 100 000 h.p. for the daily average and 2 520 000 h.p. on peak. By scrapping the most inefficient plants (marked 2, 3, and 5 on Fig. 1) and building new plants of modern type to utilize the 220-ft. head from above the Upper Rapids to the Maid-of-the-Mist pool, the maximum development under present recommendations would be increased to a daily average of 2 500 000 h.p., and, with the Federal Power Commission's ratio, to about 3 000 000 h.p. on peak. Thus, recommendations have already been made which would permit a total development of power twice as great as that provided by the existing plants.

It is probable, however, that more than 40 000 cu. ft. per sec. may be diverted around the Lower Rapids without serious impairment of their scenic beauty or their ice-discharging capacity. If the total quantity recommended for diversion around the Falls were permitted to be diverted also around the Lower Rapids, the total development would rise to 3 000 000 h.p. average and 3 600 000 h.p. peak. From that point onward the ultimate development of Niagara can be estimated only by determining the minimum quantity of water required to preserve a satisfying scenic spectacle.

When the limits of diversion consistent with the preservation of a satisfactory scenic spectacle are reached, it is probable that it will become necessary to find means to utilize as much as possible of the flow of the river during the night hours when scenic effects may be disregarded. This may be done by installing additional capacity in industrial plants to be supplied with power only during the night hours, or by substituting hydro-electric power for steam power to save fuel that would otherwise be burnt at night, or by storing the water for use at hours of peak load during the day. The greater value of peak power, which results from the instinct that leads most people to prefer to work during the day and sleep at night, may tend to offset the cost of storage. Such expedients as these will probably form part of the ultimate development of Niagara Falls.

It is most important to remember, however, that at this moment it is not at all necessary to decide how far Niagara power development, ultimately, may be carried. The preservation of a satisfactory spectacle may be insured by a step-by-step development of power and scenery together. A diversion of 20 000 cu. ft. per sec. is sufficient water for the first step; this will provide for power development on a sound economic basis. As each development is made, its effect on the scenery may be noted, and if necessary remedial works

may be provided. It is beyond question that the logical step immediately required in the development of Niagara power is the construction of the remedial works recommended by the Board and a new plant on the American side under a head of 312 ft. to utilize initially not less than 10 000 cu. ft. per sec. and produce not less than 300 000 h.p.

## Bibliography

Many references to Niagara plants and to the important problems involved are found in engineering literature. For convenience a number of the more important papers are listed here, under appropriate subject headings.

# DISCUSSION

THOMAS H. HOGG,[5] M. AM. SOC. C. E.—There are four headings under which the speaker desires to discuss Mr. Gibson's paper, no one of which is closely related to the others. The discussion may appear to be somewhat disconnected, but this is explained by the breadth of the field covered by the author, and the fact that almost every page of the paper opens up avenues of thought, each of which might provide discussion more voluminous than the original paper.

*Period of Service and Obsolescence.*—The historical notes with regard to the various power developments at Niagara Falls direct one's attention to the life time of the various power plants. Referring to Table 1 it will be seen that the Schoellkopf Plant was commenced in 1852 and completed in 1924. The first of these dates refers to the time at which the construction of the canal that supplied water to this plant was begun, and the last to the completion of Station No. 3-C in this plant. If one goes back to the historical notes themselves, it will be seen that Station No. 1 was built in the period from 1901 to 1904, and gave service for 23 years. Station No. 2, built in the period from 1895 to 1904, with a capacity of 33 900 h.p., was in service from 17 to 26 years, according to the particular unit being considered. These two stations gave place to larger development and have been abandoned and dismantled.

Three other plants, namely, Niagara Falls Power Stations Nos. 1 and 2, and, to a certain extent, the Toronto Power Plant, are in the reserve list; that is, while they are maintained in such a state that they may give service at any time, they are not on full operating schedule. The Toronto Plant does give daily service, but is operated more or less as a peak-load plant, and is shut down at night and frequently on Sundays and holidays. These three plants have been in existence from 20 to 24 years and have given way, to a certain extent, to plants that are more economical in the use of water. There is a third group, comprising Station No. 3-A of the Schoellkopf Plant and the Ontario Power Plant. These plants have been operated for 23 years, or more, and appear to have a great many more years of service before them. The remaining developments have given 6 to 10 years of service, and are not of interest in considering the useful life of a plant, as they are perfectly modern and no appreciable changes have taken place since they were built.

It will be observed that certain plants have gone out of service at about the end of twenty-five years, and certain others have gone into reserve in about the same time. From this one might be led to assume that twenty-five years is about the useful life of these developments. It should be noted, however, that the pioneer plants, which have been dismantled, have only disappeared in part, as the canal used to supply them with water seventy-five years ago is still in service—enlarged, it is true, for greater service—and the advances in demand for power made the space occupied by these pioneers of very great value for enlarged development.

[5] Chf. Hydr. Engr., Hydro-Electric Power Comm. of Ontario, Toronto, Ont., Canada.

An examination of the Ontario Power Conduit No. 1 in 1922 by an independent Commission, led to a report that the life time of such a conduit, in contact with Niagara water, would probably be at least 40 or 50 years. The tail-race tunnels of the Toronto Plant and the Edward Dean Adams Plant are apparently in as good condition to-day (1928) as when first put into service, so that one may conclude from experience with the older plants that the water channels have a life time far in excess of the period during which any plant at Niagara Falls has yet operated. It seems reasonable to conclude, therefore, that with proper maintenance, 30 to 50 years of service may be expected from these power developments. For the modern plants, 50 years seems reasonable, because the entire development in each case is so highly efficient that obsolescence can scarcely be effective in causing the abandonment of the plant.

*Water Levels on Lake Erie.*—The speaker would like to submit a record of water levels on Lake Erie during the storm of December 8, 1927. The author refers to the variation in level on the lake, due to certain winds of high velocity and changes in atmospheric pressure. On the date named, a very strong west wind caused a considerable change in the water level at Buffalo, N. Y., the lake surface rising from 571.1 ft. at 3:00 A. M., to 579.8 ft. at 9:00 A. M. Fig. 13 shows records of maximum and minimum water levels at various points along Lake Erie and on Niagara River during the time of this storm.

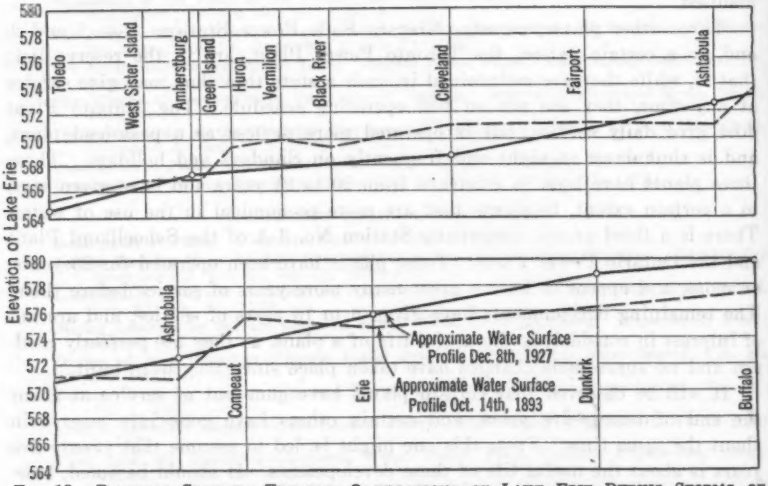

FIG. 13.—PROFILES SHOWING EXTREME OSCILLATIONS OF LAKE ERIE DURING STORMS OF OCTOBER 14, 1893, AND DECEMBER 8, 1927.

These curves indicate a lake surface elevation of 564.5 at Toledo, Ohio, at the west end of the lake, and, at the same time, an elevation of 579.8 at Buffalo, at the east end of the lake. Intermediate readings are consistent with these and show a fairly uniform variation in lake surface elevations from end to end. Fig. 14 gives records of water levels at the various points on

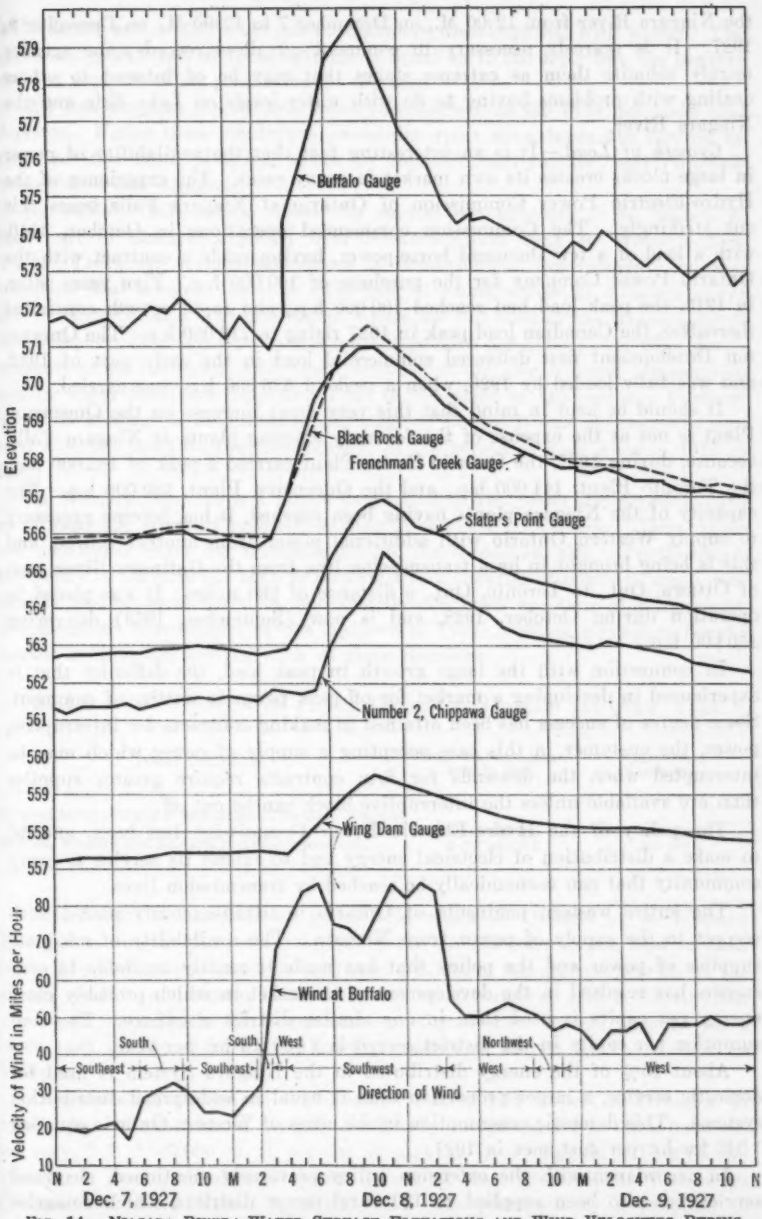

FIG. 14.—NIAGARA RIVER: WATER SURFACE ELEVATIONS AND WIND VELOCITIES DURING STORM OF DECEMBER 8, 1927.

the Niagara River from 12:00 M., on December 7 to 12:00 M., on December 9, 1927. It is scarcely necessary to comment on these records; the speaker merely submits them as extreme stages that may be of interest to others dealing with problems having to do with water levels on Lake Erie and the Niagara River.

*Growth of Load.*—It is an interesting fact that the availability of power in large blocks creates its own market in many cases. The experience of the Hydro-Electric Power Commission of Ontario at Niagara Falls bears this out strikingly. The Commission commenced operations in October, 1910, with a load of a few thousand horse-power, having made a contract with the Ontario Power Company for the purchase of 100 000 h.p. Five years later, in 1915, the peak load had reached 100 000 h.p., and rapid growth continued thereafter, the Canadian load peak in 1927 rising to 713 000 h.p. The Queenston Development first delivered commercial load in the early part of 1922, and was fully loaded by 1926, when a peak of 525 000 h.p. was carried.

It should be kept in mind that this very great increase on the Queenston Plant is not at the expense of the formerly existing plants at Niagara Falls, because, during 1927, the Ontario Power Plant carried a peak of 182 000 h.p., the Toronto Plant, 141 000 h.p., and the Queenston Plant, 529 000 h.p. The capacity of the Niagara plants having been reached, it has become necessary to supply Western Ontario with additional power from another source, and this is being brought in by a transmission line from the Gatineau River, east of Ottawa, Ont., to Toronto, Ont., a distance of 260 miles. It was placed in operation during October, 1928, and is now (September, 1929) delivering 150 000 h.p.

In connection with the large growth in peak load, the difficulty that is experienced in developing a market for off-peak power is worthy of comment. Some degree of success has been attained in making contracts for interruptive power, the customer in this case accepting a supply of power which may be interrupted when the demands for firm contracts require greater supplies than are available unless the interruptive block can be cut off.

The policy of the Hydro-Electric Power Commission has been, and is, to make a distribution of electrical energy and to extend its service to every community that can economically be reached by transmission lines.

The entire western peninsula of Ontario is advantageously placed with respect to the supply of power from Niagara. The availability of adequate supplies of power and the policy that has made it readily available to consumers has resulted in the development of a market in which probably more energy per capita is used than in any similar district elsewhere. The consumption per capita in the district served is 2 060 kw-hr. per year.

About 15% of the energy distributed in the Niagara System is used for domestic service, a larger proportion than is usual in widespread distribution systems. This domestic consumption in the cities of Western Ontario equalled 1 340 kw-hr. per customer in 1927.

In accordance with the extension policy previously mentioned, electrical service has also been supplied to 120 rural power districts, which comprise 211 townships, the majority of these being in the Niagara System. In all,

9 757 farms and 15 526 other rural customers were supplied with power. The combined peak loads of these systems is equal to 15 000 h.p.; but the benefits derived are out of all proportion to the load.

All fuel supplies for Ontario must be imported, as the Province lacks coal deposits. Under these conditions, decidedly great advantages are derived by the Province from Niagara power in industry, agriculture, and domestic convenience and comforts.

In Table 4 the author shows the capital per kilowatt to be higher in that part of Ontario supplied with Niagara power than in Western New York. There are several differences in conditions of development and distribution that account for this. The largest single source of Niagara power for Western Ontario is at Queenston, where the full head of the Niagara River is developed. This is a type that is more expensive per horse-power than developments around Niagara Falls itself, because of the long channel necessary to convey water from the Chippawa Pool to the plant at Queenston. Furthermore, on account of an imminent shortage of power, it was necessary to proceed with the work on this development at the period of high costs in 1918 to 1921.

In Western New York a larger proportion of the power developed is used at or near the point of production than is the case in Ontario. Thus, there are additional costs for transmission on the Canadian side. Furthermore, the policy in Ontario has been to provide ample supplies of power to small consumers and to rural districts, and distribution costs are thus also increased. A comparison that illustrates this is shown in Table 5, which gives data for the largest corporation serving each of these districts.

TABLE 5.—Comparison of Power Output in Ontario and New York.

| Power Company. | Total kilowatt-hours sold in 1927. | Customers served. |
|---|---|---|
| Hydro-Electric Power Commission of Ontario-Niagara System | 2 644 528 360 | 394 567 |
| Buffalo, Niagara and Eastern Power Corporation | 4 237 842 392 | 259 087 |

Table 5 does not include all power sold either in Ontario or in Western New York, but the figures cover, by far the greater part of the field in each case. The transmission system in Ontario, carrying a larger proportion of the energy sold to a distance from the point of generation, and a distribution system to reach the much larger number of customers served, account for a large part of the difference in cost per kilowatt shown by the author in Table 4.

*Recommended Diversions.*—The author states, with respect to diversion of water, that "the maximum diversions officially recommended to date, however, are only * * * 40 000 cu. ft. per sec. around the Lower Rapids." This recommendation is contained in a Joint Report of the International Waterways Commission, dated March 3, 1908, which was prompted by a proposal to grant rights to divert that much from the Lower Rapids on the American side

of the river. At that time little intensive study had been made of the lower river, and any one estimating the reasonable diversion from that part had very little information to guide him. It was then considered that no more than the quantity named in the report might be diverted without impairing, to a dangerous degree, the ice-carrying capacity of the river. There have been three serious ice jams in the lower river since 1908, and in every case they have commenced at the mouth of the river and then worked up stream. The rapids section of the river remained open or cleared itself of ice quickly, even at periods when very large quantities were running, indicating that this is not the critical part of the channel.

If water is diverted from the Lower Rapids for development of power, it will be returned immediately below the rapids, and so would not adversely affect that part where ice jams have formed; the whole natural flow would still continue in the long critical reach from the rapids to Lake Ontario. Recent and more complete studies than could be made by the International Waterways Commission when the 1908 report was presented, expressing the opinion quoted therefrom by the author, indicate that a much larger diversion than 40 000 cu. ft. per sec. is reasonable. It has always been the contention of Canadians that the diversion of 36 000 cu. ft. per sec., allowed in Canada under the Boundary Waters Treaty, is not limited as to the point of return to the river, the treaty being silent in that regard. The speaker, therefore, cannot agree with the limit suggested by the author.

To complete the data supplied by the author the following unit efficiencies should be added to Figs. 8, 9, and 10, respectively: 67.0%, Toronto Power Plant; 87.5%, Ontario Power Plant; and 91.0%, Queenston Plant.

FRANK M. WILLIAMS,[6] M. AM. SOC. C. E.—The paper contains considerable interesting historical as well as engineering information. The author has traced, very clearly, successive steps in power development at Niagara Falls which by the end of the Nineteenth Century had progressed to a stage that marked it as one of the outstanding features of engineering achievement in that century.

By a system of diagrams which accompanies the paper, he has traced the progressive stages of development in the various power plants that have been constructed at the Falls. Some of these plants are shown to have been reconstructed or even entirely replaced by more effective developments.

He also has outlined the areas of the United States and Canada to which electric energy generated at the Falls has been transmitted and the benefits which have been obtained, due to the reasonable price of the power thus made available. These benefits are demonstrated by the great manufacturing and industrial developments which have been built up in this territory.

It was not until the advantages to be obtained by the use of this cheap power led to a demand for a greater amount of it that alarm began to be felt as to the injury which was being done, or which might be done, to the scenic beauty of Niagara Falls because of diversion. As is usual in cases of this kind, the remedies suggested were considerably in excess of the danger. These remedies took the form in the first place of legislative acts, which had their bases in the

[6] Cons. Engr., Albany, N. Y. Mr. Williams died on February 20, 1930.

feeling on the part of the admirers of the scenic beauty of the Falls and the adjacent portions of the Niagara River that permanent injury to that beauty was imminent. The Falls of Niagara are so well known to a majority of the people of the United States and to foreign visitors that perhaps it is natural that some such alarm might be felt. However, it seems apparent as a result of the various studies that have been made and the investigations that have taken place that there is not so much danger to be feared from a further diversion, accompanied by certain proposed compensating or equalizing construction in the bed of the river, as there is in the natural recession of the Horseshoe Falls. This recession is likely to continue until the beauty of these Falls is greatly impaired unless a preventive is found in some of the remedial works suggested.

The more recent trend of events leads to the hope that something of the kind may be attempted in the near future and that in the process of the undertaking a greater diversion for power purposes may be permitted while, at the same time, permanently preserving the features of scenic beauty.

There are complications in accomplishing this, resulting from the fact that several Governmental parties are concerned, namely, the United States, the Dominion of Canada, the Province of Quebec, and the State of New York. The latter has set up a Water Power and Control Commission which has taken the position that the State of New York is the owner of substantial rights at this location.

The problem as to a definite determination of proper balance between the economies to be generally effected by a larger diversion and the element of scenic beauty to be preserved is one of some difficulty, and because of what might be termed a four-party governmental interest, anything that may be accomplished in this respect in the way of greater diversion takes time. This accounts largely for the fact that up to the present, limitations as to the quantity of water to be diverted for power purposes have not been enlarged.

The author suggests that the first step should involve an additional diversion of 20 000 cu. ft. per sec. and that whatever part of it may be developed on the American side should be on a head of 312 ft. He presents data to indicate that the amount of additional diversion at least could safely be made without affecting the permanent beauty of the Falls or of the Gorge. It might even be beneficial in withdrawing from the Canadian side of the river a part of the flow which is causing the recession at the apex of the Horseshoe Falls. This seems a reasonable and sound suggestion. In the speaker's opinion it can safely be made, within the limitations as to diversion which may be arrived at later, when some agreement has been reached as to the character and extent of the proposed remedial works. This should permit of a diversion much in excess of the present total of 56 000 cu. ft. per sec.

There has been some question as to diversions which might be made around the Lower Rapids. This has been under serious contemplation recently by some of the hydro-electric interests, that own riparian rights in this locality. Applications for licenses have been filed with the various Governmental authorities looking toward such diversion. If the total diversion around the Falls

is limited to the present amount, then the diversion around the Lower Rapids might well be made. If, however, the total authorized diversion for power purposes around the Falls should reach more than 100 000 cu. ft. per sec., a considerable part of which would be utilized in an over-all development, it might well be found that a diversion around the rapids and the whirlpool is not practicable.

CHARLES KELLER,[7] M. AM. SOC. C. E.—The speaker intends to confine his remarks principally to some amplification of Mr. Gibson's historical account and to discuss the remaining outstanding problem, namely, the formulation of a wise and statesmanlike permanent international policy as to further diversion and development of water power.

The author's account of the manner in which the United States gained control of diversions of water for power purposes on the east side of the Niagara River at and above Niagara, N. Y., does not, perhaps, lay sufficient stress on some details that should be understood by all who are seeking to participate intelligently in the correct decision of questions of public policy.

For example, the National authority over the diversion of water for power purposes at Niagara Falls is, to-day, accepted as a matter of course by most people who have any occasion whatever to think about it. Those who wonder whether, after all, there is any legal justification for the exercise of such authority are few in number, possibly because, among those who are at all interested, it is believed that the Federal Water Power Act has definitely settled the legal status in favor of National control.

Since 1917 there has been a great invasion of the domain of authority formerly supposed to be reserved to the States, but seemingly this has been in keeping with existing public opinion. At any rate, there has been little active objection on the part of the general public.

The case was different before 1910 when the present tendency to broad construction and, sometimes, complete disregard of traditional limitations of constitutional authority, did not exist. Accordingly, when the Burton Act of June 29, 1906, was passed, there was considerable doubt, in Congress and elsewhere, as to its constitutionality. If it were to be considered constitutional, it must derive its authority from the oft-invoked right "to regulate commerce with foreign nations and among the several states and with the Indian tribes".[8]

Notwithstanding this doubt as to jurisdiction, the two power companies submitted to the restrictions of the Act and co-operated, with liberal good will, in the investigations inaugurated by the United States Lake Survey for the purpose of arriving at a conclusion as to the amount of the diversion which, to quote the language of the Act, "* * * shall not injure or interfere with the navigable capacity of the river, its integrity or proper volume as a boundary stream, or the scenic grandeur of Niagara Falls."

At that time, there was no evidence to support an assertion that the power diversions had any effect on "the navigable capacity of the river" and yet this

[7] Brig.-Gen., U. S. A. (*Retired*); with Byllesby Eng. & Management Corporation, Chicago, Ill.

[8] Section VIII, Paragraph 3. of the Constitution of the United States.

was the only consideration mentioned in the Act that would come within the constitutional grant of power and justify the restriction of power diversions to 15 000 cu. ft. per sec., imposed by the War Department under its terms.

The New York companies, however, acquiesced in accepting the regulatory control of the United States. While, later, the investigation disclosed that three out of the five major power diversions in the United States and Canada did affect the level of Lake Erie and the depths in the Niagara River between Lake Erie and the points of diversion, the effect discernible at that time was small, the proof of its existence perhaps arguable, and the actual material result very slight.

Then, as now, the power companies were good citizens, observant of the decencies that should characterize the relations between citizens and their Government. Indeed, they went further and, in a matter certainly far removed from the National jurisdiction, showed a public spirit as enlightened as it was gratifying. This refers to their voluntary co-operation with the Commission created by the Secretary of War in 1906, for the purpose of remedying unpleasant scenic conditions on the New York side. Certainly, such a matter concerned, not the National or the State, but merely the local, authorities; and yet the two power companies not only accepted advice but originated suggestions for improvement, and, without protest, paid the expense of these scenic betterments. They certainly were pioneers in what is now referred to as "public relations".

Later, came the treaty proclaimed May 13, 1910, certain provisions of which have been mentioned by Mr. Gibson. Article V of this treaty authorized diversions from above the Falls of not exceeding 20 000 cu. ft. per sec. in New York State and 36 000 cu. ft. per sec. within the Province of Ontario, Canada. At that time the restrictions of the Burton Act on diversions in New York State were in force and the two New York companies were permitted to divert, between them, a total of only 15 100 cu. ft. per sec. Notwithstanding repeated efforts by the power companies to secure authority to increase their diversions to the treaty limit, that is, to divert 4 400 cu. ft. per sec. additional, the War Department held that the will of Congress was shown, not by the treaty but by the terms of the Burton Act. Even after that Act expired in 1913, the War Department continued to enforce its limitations rather than those of the treaty. Meanwhile, the three Canadian companies were approaching closer and closer to the treaty limit of 36 000 cu. ft. per sec. laid down for Canada. At this later day, in the perspective of the years that have passed, the speaker is unable to see the wisdom of this unilateral policy of the War Department.

The demands for increased production in Canada created by the World War caused considerable irregularity in, and curtailment of, the supply of power transmitted from the Canadian side into Western New York. At the same time, war orders for the Allies had increased the power load on the New York side to such an extent that the Buffalo General Electric Company, theretofore operating exclusively on Niagara Falls power, decided to build a steam plant. Pending the completion of this plant, this company sought, and obtained from the War Department, permission to increase temporarily the diversion made at the Edward Dean Adams Station. An increase of 1 500 cu. ft. per sec., the

equivalent of perhaps 10 000 to 12 000 kw. of additional power for the Buffalo market, was allowed with the understanding that this permission would cease with the completion of the first unit of the steam plant.

Then the United States entered the war, and after that followed the greatest industrial activity the country has ever known. Then, too, came reason to regret the failure of the United States to authorize the fullest possible use of Niagara water for power purposes permitted under the treaty. The supply of water power at Niagara Falls, then about 275 000 h.p., if used exclusively for the manufacture of electro-chemical products essential for war purposes, would probably have been insufficient for war needs, but much of this power was required for the commercial and domestic loads at Buffalo, N. Y., and at points between Buffalo and Niagara Falls. Obviously, it was necessary to continue to supply the normal electric requirements for public and domestic lighting, for street railways, and for countless other purposes incident to the transaction of the daily business of the population, and, until other possibilities were exhausted, good policy demanded the continuance of the temporary permission for increased diversion. In the fall of 1917, the need of energy for war purposes in and near Niagara Falls became so serious that the Secretary of War was forced to intervene and shortly thereafter steps were taken to requisition and to allocate the available power supply in accordance with an orderly system of priority.

The two power companies at Niagara Falls submitted gracefully to this regulation of and interference with their business and did their utmost to promote the war program of the Government. Later, when the agents of the Secretary of War sought means to increase the power supply of this district, an attempt was made to secure legislation authorizing the diversion of 4 400 cu. ft. per sec., the unused portion of the treaty water. Several months were wasted in this effort and, when it became evident that legislation could not be had and that the supply of certain strategic war materials, obtainable only, or chiefly, at Niagara, would probably soon fall short, the War Department finally adopted the only available alternative and, reversing the policy of eight years' standing, decided to issue a revocable license for the utilization of the 4 400 cu. ft. per sec. remaining from the treaty allotment. At about the same time, negotiations were begun, looking toward the consolidation of the two then existing power companies. Here, again, effective progress was dependent on the active co-operation of the two companies and their willingness to expend many millions of dollars, at a time when money was hard to get, on the faith of a revocable permission, an authorization the permanency of which was at least speculative. It is mere justice to those who controlled the two companies to state that they showed no disposition either to haggle or to hesitate and that, when their help seemed necessary to the execution of part of the comprehensive plan for obtaining a power supply adequate for the war program forecast by those in authority, they were prepared to do their share promptly and without asking the financial assistance of the Government.

In short, it took war and war's imperative needs to bring into effective use for the benefit of the people of Western New York the full diversion of water

allowed to be made under the 1910 treaty. This appears to be one of the few real advantages that have followed any war.

There may be some, however, who, basing their doubt on the loss of beauty or landscape values, question whether increased diversion from above the Falls results in a net gain to the entire public, and this leads to a brief consideration of the policy that, in the best interest of the entire public, ought to be observed in the future. Mr. Gibson refers to the proposals made by those who, in one capacity or another, have been in a position to offer counsel. These proposals, while differing among themselves, are consistent in that they assume that the beauty of the Falls is of prime importance and must be protected from deterioration due to natural causes and from diminution due to works of Man, including diversions for power purposes. The various proposals range over a wide extreme, there being, on the one hand, those who deprecate all changes in the Falls on the grounds that Nature is more to be trusted than Man and that all changes, for whatever purpose, are likely to be damaging. The proponents of this belief probably regard themselves as the only real conservationists and defenders of the integrity of the Falls. The other extreme is occupied by those who take the utilitarian view that was summarized by the author in the quotation attributed to Lord Kelvin.

Between these extremes are found the opinions of those who feel that Niagara Falls as a spectacle has in the ages suffered more from the unrestrained processes of Nature than it has ever suffered from the works of Man; that natural forces now visibly at work must be neutralized, or their ill effects counteracted; that it is not possible for the human eye or judgment to appraise the relative beauty and impressiveness of the Falls when their discharge varies over a comparatively wide range, a decline of beauty in one aspect being compensated by an enhancement elsewhere; that, most probably, the great appeal of the Falls is based upon a general impression rather than on appreciation of local details; and that, beyond a volume that satisfies the eye and ear of the average visitor, further discharge is neither desirable nor useful. Those who take this middle attitude feel certain that the correct eventual policy will include the utmost amelioration of the appearance of both Falls and the retardation or prevention of the destruction of the Horseshoe Falls, and, as an incident, will provide for such increase in power diversions as is called for by this enhancement of the beauty of the Falls.

The policy will be based upon an orderly program of remedial work, such as that for spreading the discharge over the Horseshoe Falls, followed by observation of results due to varying the power diversions over the widest permissible range and, in turn, by such further remedial and compensating work as may be indicated to assure permanently satisfactory scenic conditions at Niagara and unimpaired channel conditions at Buffalo and on Lake Erie when power diversions have been increased. Those who favor this policy of combining remedial work and improvement of the Falls with the utmost increase in diversion consistent with really significant scenic values are better and broader conservationists than the first-named class because they give thought to the conservation of human happiness and welfare as well as of scenic grandeur.

In this middle school of thought, differences exist as to the ultimate limit of permissible diversion from above the Falls, but all agree that it should be the maximum that can be spared without doing appreciable harm to scenic values. In other words, they feel that power values are almost as important as scenic considerations and that the prosperity and contentment of 5 000 000 permanent residents presents to the unbiased judgment a thoroughly pleasing picture, one that should be weighed in the scale with the casual impressions of 2 000 000 visitors who annually spend a few hours at the Falls.

The speaker's view is identical with that recommended in the report of the Board of Engineers for Rivers and Harbors of 1920, namely, that the total diversion may ultimately reach 100 000 or 110 000 cu. ft. per sec. This is, of course, merely an opinion, but it is based on some familiarity with scenic conditions and with the changes in them during a period when the power diversions have increased from about 30 000 cu. ft. per sec. to nearly 56 000. This report recommended compensating and remedial measures, with step by step increase in diversion and careful observation of the effects of the remedial works and of the progressive increases in diversion. With these remedial measures, it was thought that the maximum diversion mentioned would leave the Falls more beautiful than they had been within the memory of persons now living. Since this report was made, conditions have changed and the rate of diversion may now be varied over a wide range. The effect of the remedial works can be observed, therefore, under greatly varying discharge conditions, and judgment can be formed as to further operations.

Any further development of power should utilize the maximum available head as far as can be done without detriment to the rapids below the Falls. The consensus of opinion is that the limit is a total diversion of about 40 000 cu. ft. per sec. from these rapids, leaving 24 000 cu. ft. per sec. still to be developed, provided it is decided that the existing diversion from above the Falls may properly be increased to that extent. Incidentally, it should be said that the course of the river below the Falls is such that the conduit for such an over-all development on the New York side will be less than one-third the length of the head-race channel of the Queenston Plant. It seems likely, therefore, that if by some statesmanlike agreement, frontiers could be disregarded, the greatest economy could be attained by developing the power of any future over-all diversion in a single plant on the New York side.

Nothing has been said about the engineering features of the six existing water-power developments. They present an interesting picture of progress from the standpoint of mechanical, electric, and hydraulic engineering, culminating in the large units of the Queenston Plant and of Section 3-C of the Schoellkopf Station.

The water power of Niagara Falls is continuous and constitutes an absolutely dependable source of energy backed by the greatest reservoir system known to Man. It is subject to just as little chance of interruption as is steam-generated energy, and it is considerably less costly when delivered on the switchboard available for send-out. Mr. Gibson is conservative in his statement as to the economic value of this particular variety of water power and

the speaker feels that, despite the constant improvement in steam-driven machinery, the day will never come when Niagara energy will be superseded.

The case is otherwise with most of the now undeveloped water-power sites in this country. Their development would either result in stream flow plants with discontinuous output or they would require the provision of adequate storage, which would usually be extremely expensive, or supporting steam capacity would be necessary. No great margin exists for further improvement in efficiency of water-power equipment, with water-wheels now producing 94% of the theoretical energy content of the water. On the other hand, steam equipment still has far to go; the efficiency of equipment from the boilers to turbines is certainly not more than 30 per cent. It seems safe to state that many water-power sites of the character just mentioned will probably never be developed, or, at any rate, they will not be put to use until the cost of fuel is much greater than at present.

This makes it clear that, generally speaking, the so-called conservationists and those who make political capital out of undeveloped water power as being the one natural resource still in the possession of the people and who preach that it is desirable to protect this resource from exploitation by the private capital are wide of the mark. If they are sincere, they should rather support a National policy under which these second-rate sites may be developed at the lowest possible cost and thereby promote the conservation of the coal supply of the nation. Obstructions and difficulties placed in the way of the utilization of such sites are detrimental to the general public interest and have already resulted in the abandonment of projects for developing many of them.

William Kelly,[9] M. Am. Soc. C. E.—The author has treated, rather briefly but comprehensively, the question of the regulation of the Great Lakes System. This has been a controversial question for thirty years or more, and one still hears many divergent opinions. The speaker, as a member of the Joint Board of Engineers on the St. Lawrence Project, was called upon to give the subject considerable study. Any one who will read the principal reports that have been published, will probably agree that most of the divergence of opinion is due to incomplete consideration of a very far-reaching problem. The following statements are quite easy to prove, and are generally accepted:

1.—Fluctuation of lake levels can be reduced, but only to a limited extent.

2.—Reduction of the fluctuation of lake levels will decrease the storage available for regulating outflows, and, therefore, will produce greater fluctuation in the flows of the Niagara and St. Lawrence Rivers.

3.—The low-water flow of the St. Lawrence River cannot be reduced, nor can the high-water flow be increased without serious damages.

4.—Fluctuations in the flows of the Niagara and St. Lawrence Rivers can be reduced only by increasing the available storage in the lakes, which means increasing their fluctuations.

5.—The high-water level of the lakes cannot be raised because of the very extensive flowage damages that would result.

[9] Col., Corps of Engrs., U. S. A.; Vice-Pres., Buffalo, Niagara & Eastern Power Corporation, Buffalo, N. Y.

6.—The surface of the Great Lakes constitutes about one-third the total drainage area tributary to them. In their natural condition, therefore, they provide so high a degree of regulation that under the law of diminishing returns no great profit can be looked for from greater regulation.

The Great Lakes System covers a vast area and has important effects on many diverse interests in two countries, several States and provinces, and many cities. It is failure to consider the effect of regulation on all these interests that causes most of the disagreement. A few examples may illustrate some of the difficulties:

(*a*) If the fluctuations of Lakes Michigan, Huron, and Erie are reduced, the fluctuations of the flow of the Niagara River will be increased to the detriment of power and navigation interests on that river; the fluctuations of Lake Ontario will be increased to the detriment of riparian owners and of navigation thereon; and the fluctuations of the St. Lawrence will be increased to the detriment of riparian owners and navigation above Quebec, Que., and of power interests above Montreal, Ont., Canada. Calculations show that the damages far outweigh the benefits.

(*b*) Mr. Gibson shows that an attempt to regulate the flow of the Niagara River so as to keep the minimum flow from falling below 180 000 cu. ft. per sec., which has been proposed as an aid to power development, would result in the production of about 2 000 000 000 kw-hr. per year, which is less power than can be obtained from the natural flow available 50% of the time. At the low figure of 2.8 mills per kw-hr., this loss would capitalize at about $100 000 000 and, at the cost of steam power, which would eventually have to replace it, the capitalized loss would be more than $200 000 000. The Joint Board of Engineers on the St. Lawrence Project found that regulating the flow of the St. Lawrence to increase the minimum flow would have a similar effect upon power developments on the St. Lawrence.

Many other examples of the difficulties involved in regulation can be given, but those who are not convinced by Examples (*a*) and (*b*) probably cannot be convinced unless they make complete studies themselves, carrying them far enough to determine what will result from their proposed regulation all the way down to Quebec on the St. Lawrence River. The Joint Board made very laborious computations to determine the effects throughout the Great Lakes System of all the practicable plans of regulation that had been proposed. As a result, the Board found that:

"The regulation of Lake Superior has been satisfactory to the two countries for the reason that the fluctuations introduced in discharge from that lake are absorbed in the great reservoir formed by Lakes Huron and Michigan without greatly affecting the levels of the latter or materially affecting the discharge of the Niagara and the St. Lawrence Rivers."

* * * * * *

"The regulation of Lake Ontario, proposed as a necessary part of the improvement of the St. Lawrence, affects only Lake Ontario. Its regulation will not affect, in any substantial manner, divergent National interests."

* * * * * *

"The regulation of the lakes, as a whole, is an entirely different matter."

While the Board was unable to find any economically feasible method of regulating the outlets of Lakes Michigan, Huron, and Erie, it did find it "advisable to construct compensating works in the Niagara and St. Clair Rivers to counteract the effect of all diversions and outlet enlargements on the levels of Lakes Michigan, Huron, and Erie."

R. D. JOHNSON,[10] ESQ. (by letter).—The author has touched upon the direct benefit accruing to a large population and the indirect benefit to the whole country through the distribution of Niagara power, which is sold much cheaper than the average in other territories less favorably situated. He has effectively disposed of a misconception that power development at Niagara Falls has affected the level of Lake Erie. He makes clear the difficulty, if not the futility, of attempting to regulate the lake level either to diminish its fluctuations or to improve the flow of the Niagara River, but he does point out the great desirability of modifying the discharge over the Horseshoe Falls and increasing the flow over the American Falls, both as an assurance of the preservation of scenic values and as a means of releasing additional water for power purposes. A very important point in his recommendation is the fact that this work may progress gradually, testing each phase of the situation by measurements and observation, so that there is not the slightest danger of having to depend solely upon pre-determined engineering computations for the ultimate result.

Mr. Gibson's values of revenue received from the sale of Niagara power brings to mind immediately a popular misconception as to the intrinsic value of undeveloped water power in the minds of many, although it is believed their number is decreasing. A notion seems to have grown up that water power costs very little because Nature so easily furnishes the water as compared, for example, to the arduous mining and shipping of coal. It is this naive idea, perhaps, that has been largely responsible for a great deal of Socialistic propaganda that the natural water power belongs to the people and that private interests should at least be heavily taxed by the Commonwealth for the privilege of developing and distributing such power. A water-power site, in general, only becomes valuable and able to compete with other kinds of power when: (1) The topography favors development; (2) the flow is dependable; (3) the very best of engineering talent is brought into play; and (4) the location is not too far from the power market.

Niagara power has the benefit, to a marked degree, of these four requisites, but it should not be forgotten that its great success to-day is due to the highest quality of engineering skill.

While it is true that, when a favorable water-power site has been skilfully developed in the vicinity of a proper market, it may deliver cheap power, yet it is quite as true that even a favorable site may cost so much to develop, because of ineffective design and blunders, to say nothing of the great risk always involved in corralling and handling large volumes of water, that the perpetual interest charge will run the cost above that of other kinds of power. It is clear to those well versed in this subject that private enterprise is just as proper and effective for the public good in water-power development as

[10] Hydr. Engr., New York, N. Y.

in any other branch of public utilities. Even what might be regarded as a simple extension of the present Niagara power development could easily be almost ruined from an economic standpoint if not undertaken by those who have spent their lives at this business and in that locality.

To sum up, then, it should be understood that the great economic benefit to the whole population of the further development of the remaining available water-power resources is only possible to the fullest extent when carried out with the strictest competitive economy such as is well known to result from private enterprise. That the benefit of such economy is necessarily passed on, either directly or indirectly, to all the people is an important point of Mr. Gibson's paper.

GLEN E. EDGERTON,[11] M. AM. SOC. C. E. (by letter).—The author has pointed out clearly the prominent place that the Niagara Falls power plants have taken in the development of the art of hydro-electric power generation. The utilization of this natural resource is not yet complete, and its problems will continue to occupy a conspicuous position in the future as they have in the past. Great credit is due the individuals who have contributed to the solution of these problems. Although such credit may not have been fully accorded, it is significant that many of the most prominent engineers with whom the writer has come in contact, in connection with water power development throughout the United States, have been associated at some time in their careers with the Niagara Falls development.

The pre-eminence of Niagara Falls power in the water-power industry is paralleled by its prominence in the affairs of the Federal Power Commission. The first license issued under the Federal Water Power Act of June 10, 1920, covered the existing plants on the American side. The application for a license was submitted originally on July 1, 1920, before the Commission was fully organized for the transaction of business. Nine other applications for power development involving the Niagara River were submitted to the Commission, which gave them final consideration at a meeting of February 28, 1921, and authorized a license to be issued to The Niagara Falls Power Company for the then existing plants and the enlargment of the Schoellkopf Station to its present capacity.

The deliberations of the Commission in these cases involved some important features of the new water policy. Among them was the practical application of Section 10 (*a*), of the Federal Water Power Act, which reads as follows:

"Sec. 10. That all licenses issued under this act shall be on the following conditions:

"(*a*) That the project adopted, including the maps, plans, and specifications, shall be such as in the judgment of the commission will be best adapted to a comprehensive scheme of improvement and utilization for the purposes of navigation, of water-power development, and of other beneficial public uses; and if necessary in order to secure such scheme the commission shall have authority to require the modification of any project and of the plans and specifications of the project works before approval."

[11] Major, Corps of Engrs., U. S. A.; Dist. Engr., U. S. Engr. Office, Rock Island, Ill.; formerly Chf. Engr., Federal Power Comm., Washington, D. C.

Before authorizing any project, it is incumbent on the Commission to determine whether it is "best adapted to a comprehensive scheme of improvement and utilization." While The Niagara Falls Power Company did present alternative schemes, including several types of over-all development, the application dealt primarily with the 215 ft. of head obtainable by diversion around the Falls only. Manifestly, this project did not of itself constitute a comprehensive development for the Niagara River to the extent of permissible diversions of water, because it left undeveloped the fall in the Lower Rapids, amounting to nearly 100 ft. It had already been established that a large quantity of water could be diverted around these rapids without injury.

The probable feasibility of over-all diversion was indicated not only by the alternative proposals of The Niagara Falls Power Company, but by two other applicants for authority to develop the total fall. The Commission, then, had at its disposal 20 000 cu. ft. per sec. of water which it could authorize for use in: (1) A development through 215 ft. of fall around the Falls, leaving the remaining fall for separate development; (2) a single development through about 310 ft.; and (3) a development using part of the water around the Falls only, with an over-all development for the remainder.

Investigation showed that the cost of development around the Falls alone gave the cheapest power. Capital costs per horse power of over-all development in a single stage would exceed those of a Falls development by about 40 per cent. Similar costs of the second stage, in a two-stage development, and the cost of the entire development in the two stages, would exceed the same figure by about 250% and 125%, respectively. Consequently, authorization of the Falls development would produce much the cheapest power immediately, but it would commit the Commission to an eventual scheme of development much more expensive than the best development, unless the latter should be postponed until the power plants at the Falls could be scrapped.

It appeared that the partial development proposed was capable of meeting the power requirements of the tributary region for several years; that the more expensive development, although economically feasible, would necessarily involve higher charges for power to the disadvantage of industries which, in some cases, owed their existence to the possibility of procuring power at minimum rates; that additional power was needed urgently and could be supplied most promptly by a partial development; that probably additional diversions could soon be authorized in connection with remedial works at the Falls so as to permit a second step in development which might embrace the entire 310 ft.; that such a step would serve the urgent needs of the power market for an extended period; and that even in the ultimate development it will probably be possible to permit greater diversion around the Falls than around the Lower Rapids on account of the requirements of the ice-carrying capacity in the latter. The relative degrees to which these and similar factors governed the final decision of the Commission can not be stated precisely, but the conclusion was reached that the Falls development proposed in the Schoellkopf Station was best adapted to a comprehensive scheme of improvement.

A license was issued on March 2, 1921, to permit the use of 19 500 cu. ft. per sec. of water, the remainder being reserved to satisfy equitable rights that seemed to be vested in certain power users along Eighteen-Mile Creek below Lockport, N. Y., by reason of long use. Of this water, 225 cu. ft. per sec., which was subsequently determined to be in excess of the quantity required to satisfy those rights, was allotted to The Niagara Falls Power Company on December 13, 1926; and since rights themselves have now been acquired in the interest of that Company, it is expected that the entire quantity authorized by the Boundary Waters Treaty will shortly be available for the Schoellkopf Station.

This case illustrates the necessity for broad and reasonable interpretation of one section (and the same necessity applies to other sections) of the Federal Water Power Act. Little criticism of the principal conclusion is possible, but it might have been held that complete physical development in the most economical way should be required immediately. The results of such a finding would have violated the economics of the situation as it existed in 1921. The reservation of a quantity of water for relatively wasteful use at Lockport and along Eighteen-Mile Creek can not be so easily established in accordance with the principles of the law.

A limitation of the maximum rate of diversion to 120% of the average rate was fixed by the Commission in its license for the American plants. The pertinent words of the treaty are, "not exceeding in the aggregate a daily diversion at the rate of twenty thousand cubic feet of water per second." If it was intended to fix the maximum rate at 20 000 cu. ft. per sec., there seems to be no significance to the word, "daily." If it was desired to fix only the quantity to be diverted in each day, it might readily have been stated definitely in acre-feet or other convenient units. There is room for disagreement as to the exact force of the phrase, but the Commission, concluding that a higher rate than 20 000 cu. ft. per sec. was permissible, also believed that the public interest required a limit which would not permit diversion at a very high rate for a few hours each day. No such specific limitation is known to govern the plants on the Canadian side, which, the writer believes, actually operate with a peak somewhat higher than 20% above the average rate of diversion.

The Federal Power Commission undertakes to preserve natural scenic grandeur and beauty wherever they are of importance in connection with any prospective license. This responsibility is considered to be a part of the obligation, laid down in the section of the Federal Water Power Act previously quoted, to insure provision for other beneficial public uses in addition to power development and navigation. Such questions have been prominent in many water-power projects beside those at Niagara Falls. Developments on Lake Chelan, in Washington; Wolf River, in Wisconsin; Cumberland River, at Cumberland Falls, in Kentucky; Arkansas River, at Royal Gorge, in Colorado; and the Potomac River, at Great Falls, in Maryland and Virginia, are conspicuous cases in which strenuous objections to the issuance of a license have been made by organizations and individuals, concerned lest the Commission might fail to recognize or to perform effectively its duty in such matters.

In the Niagara Falls case it was not considered that further studies, in addition to those which had resulted in the treaty provisions, were necessary to establish the desirability of permitting the diversions approved therein, but an article was included in the license to require the power stations to be constructed and maintained so as to blend harmoniously with the scenic features near them.

F. P. WILLIAMS,[12] M. AM. SOC. C. E. (by letter).—The outline of the power plants given in the paper not only shows the progress in the industry at Niagara Falls, but illustrates the tendency in other places to consolidate the generation of power at one location in one large plant. If space had permitted, Mr. Gibson would probably have described the difficulties, especially with bearings, in the early days which prevented development of the total head. There are many who will recall seeing the tail-water of some of the plants discharging half way down the cliff.

*Limitation of Diversion of Water Under the Existing Treaty.*—In mentioning the Chicago diversion as being one of the factors that led to the unequal diversion allotted under the treaty, Mr. Gibson doubtless gives weight to the discussions leading up to the ratification of the treaty. The treaty itself does not mention the Chicago situation. From evidence presented in the Courts, it appears that the large diversion made by the Sanitary District is illegal. Construction of works to take care of the sewage of Chicago and to relieve this condition is in progress in order to reduce the quantity to the necessities of navigation. The flow required for navigation purposes is being determined by the Supreme Court of the United States. In view of this it would appear that consideration of a greater diversion of water at Chicago than that required for navigation was without legal foundation.

*Economic Benefits.*—Mr. Gibson's view that steam improvements have not advanced to a point that will enable all water-power plants to be discarded is well reinforced by the construction of such plants that is taking place at the present time (1929) in Canada, in some parts of this country, and abroad, especially in Switzerland. It is evident that there are some factors besides the comparison with steam-generating cost which determine the feasibility of hydro-electric projects. Stability of water power, which enables its cost to be computed accurately for a term of years, and freedom from fear of interruption which confronts steam-produced power on account of possible interference with fuel supply, are among such factors. In some cases these influences are of great importance.

Further development of power at Niagara is feasible, providing works are constructed in the river to distribute the flow; the development of water power on the St. Lawrence River is economic; additional regulation by storage reservoirs will result in more hydro-electric projects being developed on the interior streams.

The statement that the company had not collected the difference between the cost of steam and hydro-electric power from the consumer, but a considerably less sum, calls attention to the industries that have been built up

[12] Secy. Engr., New York Water Power Comm., Albany, N. Y.

at Niagara Falls which require low cost power in order to exist. Until recently Niagara Falls was the center of the largest electro-chemical metallurgical industries on this Continent.

*Ultimate Diversion.*—Mr. Gibson has recognized the universal solicitude for the preservation of the scenic grandeur of the Falls. Credit for their preservation is due to the establishment of parks on both sides of the river by Government agencies; to the treaty for limiting the amount of diversion; and to the architects and engineers for the design of works so as to subordinate them and harmonize them with the surroundings as far as possible.

The author describes the plan for increasing the diversion sufficiently for an economic development rather than attempting to determine the ultimate permissible diversion. The preservation of the grandeur of the Falls appears assured as long as there is as conservative a plan for increased diversion and as long as there is as frank a presentation of the various influences.

LEWIS B. STILLWELL,[13] M. AM. SOC. C. E. (by letter).—In this comprehensive paper the author refers to the question: "What led to the adoption of 25 cycles as the standard frequency of alternating current generated at Niagara Falls?" In answer, he quotes a paragraph from the "Electrical Engineering Papers" of the late B. G. Lamme. Mr. Lamme's statement is correct as far as it goes, but further explanation of the origin of the two standard frequencies now in wide use in America, namely, 60 cycles per sec. and 25 cycles per sec., may be of interest.

The frequency originally adopted by the Westinghouse Electric Company in 1885, when that Company actively undertook the development of alternating current for commercial purposes, was 133⅓ cycles per sec. This was the frequency used by Gaulard and Gibbs in demonstrating their system in London, and the original Gaulard transformers imported by Westinghouse were designed for it. A few years later the advantages of direct connection of engine and alternator were clearly recognized, and it became necessary to select one or two lower frequencies adapted to the lower alternator speeds which direct connection implied. In selecting a lower frequency, it was necessary to consider its effect upon transformers, motors, incandescent lamps, and arc lights as well as upon the cost and performance of the alternators. Tesla's American patents covering the polyphase motor had been acquired in 1889 and serious difficulties had been encountered in trying to adapt this motor to 133⅓ cycles.

Experiments demonstrated that American arc-light carbons of that date would not give satisfactory results on frequencies lower than about 60 cycles and after a considerable period of study and experimental investigation, it was decided in 1892 to adopt 60 cycles per sec. as the Company's standard frequency for installations in which incandescent lighting, arc lighting, and motors for industrial purposes predominated. Where a large proportion of the power transmitted by alternating current must be converted to direct current for street railway or storage battery uses, it was decided to use 30 cycles.

[13] Cons. Engr., New York, N. Y.

At the time these frequencies were adopted and, in fact, for many years afterward, converters that would operate successfully on 60 cycles had not been produced. This was the controlling reason which led to the adoption of 30 cycles as an alternative frequency notwithstanding the fact that the engineers of the Company clearly recognized the advantages of a single standard.

In 1893, when formal proposals for the first three 5 000-h.p. alternators and auxiliary equipment were invited by the Cataract Construction Company, the companies submitting tenders were faced by the fact that the hydraulic turbines had been ordered and would operate at 250 rev. per min. As it was found impracticable to design two-phase alternators which, at this speed, would deliver current at 30 cycles, the first formal tender of the Westinghouse Company was for 16-pole machines which would operate at 33⅓ cycles per sec. Professor George Forbes, one of the consulting advisers of the Cataract Company, advocated 16⅔ cycles.

In the early autumn of 1893 the writer was asked by the then President of the Cataract Company, Edward Dean Adams, F. Am. Soc. C. E., whether there was any frequency other than 133⅓ cycles per sec. upon which the Westinghouse Company would be willing to bid. In response the writer expressed the opinion that 25 cycles was practicable. Mr. Adams asked him to take the matter up with his associates at Pittsburgh, and the result was a new tender based upon 25-cycle equipment. This tender was accepted by the Cataract Construction Company, and, in this way, 25 cycles was adopted as the standard frequency at Niagara.

In connection with the first alternators, it was necessary, of course, to design transformers, meters, volt-meters, watt-meters, etc., for the same frequency, that is, 25 cycles per sec.; thereafter in practically every case in which the Company undertook to supply alternators and auxiliary equipment for a frequency lower than 60 cycles per sec., 25 cycles became the standard.

In this connection, it may be pointed out that the power transmission exhibit of the Westinghouse Company at the World Columbian Exposition in Chicago, Ill., which was designed and constructed during the autumn of 1892 and the following winter, operated at 30 cycles per sec. This exhibit included a 375-kw., two-phase alternator, step-up transformers, a short transmission circuit, step-down transformers, rotary converters supplying direct-current motors and other direct-current apparatus, two-phase induction motors, and arc and incandescent lamps. In every essential, except frequency, it was the system adopted by the Cataract Construction Company. That 25 cycles and not 30 cycles was used at Niagara was due to the fact that the Cataract Construction Company had committed itself to a turbine speed of 250 rev. per min. and to the fact that one of the advisers of the Cataract Construction Company preferred a still lower frequency. In the writer's judgment experience has demonstrated that 30 cycles would have been preferable, especially in view of the fact that at 25 cycles incandescent-lamp service is not always satisfactory. Recognition of this possible difficulty was one of the reasons upon which the engineers of the Westinghouse Company based their preference for 30 cycles.

NORMAN R. GIBSON, M. AM. SOC. C. E. (by letter).—Since the discussions were for the most part additions to, rather than criticisms of, the writer's statements, there seems little need for reply other than to thank those who have so ably contributed and to express appreciation for the information they have submitted.

Mr. Hogg's interesting charts showing the magnitude and rate of daily variation in Lake Erie and Niagara River levels caused by wind, illustrate the difficulties to be solved in the problem of lake regulation. The information he has given in regard to the efficiency of Canadian plants, the growth of the Ontario power load, and the period of service and obsolescence of the plants, is an important addition to the facts concerning Niagara power.

The discussion by General Keller has amplified the historical account of power development at Niagara Falls and has explained clearly the provisions for the control of diversions from the river for power purposes. The writer is heartily in accord with the suggested orderly program "of combining remedial work and improvement of the Falls with the utmost increase in diversion consistent with really significant scenic values."

The readers of this paper will be particularly grateful to Colonel Kelly for his discussion which submits in brief form the results of a careful study of the problem of lake regulation which was undertaken by the Joint Board of Engineers. The writer is in accord with the conclusion of this Board that it is advisable only to construct compensating works to counteract the effect of all diversions and outlet enlargements on the level of Lake Erie.

Mr. Johnson has given further evidence of the economic value of water power and that these values are necessarily passed on to all consumers.

The discussions by Major Edgerton and Mr. F. P. Williams serve to indicate the viewpoint of those charged with the control of water power development under Federal and State authorities, respectively. Both point the way to early and effective co-operation in the economic development of water powers.

The writer is indebted to Mr. Stillwell for his further explanation of the origin of 25 cycles as the standard frequency of alternating current generated at Niagara Falls. As Mr. Stillwell, himself, played an important part in the early development of Niagara power, it is of a special benefit to have his authoritative statement on this question written into the record.

# REGULATION OF LEVELS, FLOW, AND NAVIGATION, NIAGARA RIVER: SUMMARY AND CONCLUSIONS OF VARIOUS STUDIES[1]

By George B. Pillsbury,[2] M. Am. Soc. C. E.

With Discussion by Messrs. Robert E. Horton, Lynn L. Davis, Theron M. Ripley, E. W. Lane, F. G. Ray, and George B. Pillsbury

Synopsis

The factors relating to the regulation of the Niagara River are summarized, and the studies made by various agencies of the regulation of Lake Erie are described. The conclusion is reached that the results of these studies have not indicated the advisability of regulating the flow of the Niagara River.

The purpose of this paper is to discuss the regulation of the Niagara River, with its widespread ramifications, and to relate the efforts that have been made to solve it. Briefly, the problem is this: To find in what manner the natural regimen of the outflow from Lake Erie through the Niagara River can be altered to produce benefits to mankind which will so outweigh the resulting injuries as to warrant the cost of constructing and operating the controlling works.

There is certainly no insuperable engineering difficulty in building a gate structure that will control the outflow of the Niagara. The problem is how to use it if built.

## Inflow, Lake Level, and Discharge

The outflow of Lake Erie is now determined by the discharge over the natural rock weir of the rapids at the head of the Niagara River. While this is a submerged weir, the back-water is almost entirely a function of the head, and the discharge varies with the elevation of Lake Erie at Buffalo, N. Y. Within the comparatively narrow limits of range of stage of the lake, the discharge varies substantially as the lake elevation, thus establishing the present balance between the storage in the lake and the outflow. The increas-

[1] Presented at the meeting of the Waterways Division, Buffalo, N. Y., July 19, 1928.

[2] Brig.-Gen., U. S. A.; Asst. Chf. of Engrs., U. S. A., Washington, D. C.

ing discharge gradually checks an undue rise in head from an excessive supply of water to the lake, and the decreasing discharge gradually checks an undue fall when the supply is deficient. At the same time the lake absorbs in storage any temporary fluctuation of supply.

The relation between storage and discharge for Lake Erie may be expressed by the statement that a rise of 1 ft. in the lake will create additional storage equivalent to a flow of 110 000 cu. ft. per sec. for 1 month; and will increase the discharge out of the lake by from 20 000 to 23 000 cu. ft. per sec., depending on the stage.

As a consequence of the present automatic regulation, the extreme variation in the monthly mean levels of Lake Erie, in the sixty-eight years for which continuous and authentic records are available, has been 4.13 ft. The highest monthly mean level was reached in June, 1876; the lowest in December, 1925. During the intervening period the lake levels had been lowered by 0.6 ft., on account of the diversions made by the Chicago Sanitary District, the Welland Canal, and otherwise. Therefore, the fluctuation of the monthly mean elevation of the lake, due to varying supply, has been only 3.5 ft. The corresponding variation in the monthly mean discharge of the Niagara River has swung from a maximum of 252 000 cu. ft. per sec., in June, 1876, to a minimum of 166 000 cu. ft. per sec., in December, 1925.

These lake levels and discharges are monthly means. The water elevation at Buffalo is particularly subject to fluctuation, due to wind and barometric pressure. During a westerly gale the water has been known to rise 8 ft. above its monthly mean level; and, again, it has fallen 4 ft. below its monthly mean. During such periods, discharge of the Niagara River as low as perhaps 110 000 cu. ft. per sec., and as high as more than 300 000 cu. ft. per sec., may obtain.

The variations in the monthly mean levels of the lake are due to fluctuations in supply, that is, to the variations in the sum of the water received from the upper lakes and the run-off of the Lake Erie Basin, less the evaporation. The maximum monthly supply of record to Lake Erie was in April, 1913, corresponding to the rainfall which created the disastrous floods in the tributaries of the Ohio in March of that year. It reached an average of 324 000 cu. ft. per sec. for a month and resulted in a rise of lake level of about 1.6 ft. During August, September, October, and November, the evaporation from Lake Erie usually exceeds the combined rainfall on the lake and the run-off from its own drainage basin, but the supply is well maintained by the inflow from Lake Huron. The minimum supply appears to have occurred in January, 1920, due to the retardation of the inflow by ice obstruction in the St. Clair and Detroit Rivers. It amounted to 126 000 cu. ft. per sec., and was accompanied by a fall of about 0.5 ft. in level.

The total supply to Lake Erie is usually greatest in April and least in October. The April supply exceeds that of October on the average by about 80 000 cu. ft. per sec. The resulting seasonal fluctuation in the level of the lake averages about 1.5 ft., and the corresponding average seasonal fluctuation in discharge, about 30 000 cu. ft. per sec.

These are the high points of the variations in the discharge of the Niagara, with its present natural regimen, and of the resulting levels of Lake Erie.

## Interests Affected by Regulation

Before considering schemes for regulation it is necessary to cast up an account of those who are affected by the discharge of the Niagara River. Since this discharge controls the level of Lake Erie, these include the navigation interests on that lake. Such navigation is a vital part of the general lake traffic. It moves yearly about 45 000 000 tons of iron ore into ports on Lake Erie, or most of that used in the iron industry on the Continent; it moves about 300 000 000 bushels of grain annually; and it moves the coal shipped from Lake Erie to the territory lying north and west of the lakes. Lake commerce is highly organized, and utilizes practically the last inch of depth available. While it is true that the limiting draft, in recent years, has been fixed by the levels of the upper lakes, no system of regulation could be tolerated which proposed to lower either the extreme low, or the average, levels of Lake Erie. On the contrary, studies heretofore made of the regulation of the Niagara have been directed primarily to improving the lake levels.

A second set of citizens of the United States and Canada vitally affected by the levels of Lake Erie is the several million residents of the cities and towns on the shores of the lake, and along the Detroit River. They are interested, primarily, in the high lake levels. The sewer systems of the low-lying districts of the cities are based on the levels of the lake as they exist at present, and would be inadequate if these levels were raised, or even if they were maintained continuously at the highest levels occasionally reached in the past. A large industrial area in Buffalo is subject to overflow at rare intervals by the extreme storm rises of the lake. If the lake levels were substantially raised, the losses would become more frequent and more extensive. It is certain that no substantial increase in the high levels of the lake, either in height or in frequency, would be tolerated.

The third class very directly concerned in the regulation of the Niagara is the vast number of those who come to enjoy the scenic beauty of the Falls, as well as those, on both sides of the border, concerned in the development of power. Their interest in an unimpaired discharge of the Niagara is too obvious to require elaboration. It is probably more important to them that what may be termed the ordinary flow be not reduced, than that occasional extreme low flows be improved.

A fourth group are those on Lake Ontario and on the St. Lawrence. Probably the most important are the navigation interests in the Port of Montreal, Que., Canada. The low-water elevation in that port is 18 ft. or more, above sea level, and depends on the slope of the St. Lawrence below Montreal, which, in turn, is maintained by the volume of discharge. While it is true that the storage in Lake Ontario will "damp out" any temporary fluctuations in the outflow of the Niagara, yet any systematic retardation, continuing over several months, will be felt at Montreal. It is not enough that the minimum flow be kept at a point higher than that to which it has actually fallen in the past; the normal average low-water flow during August, September, October, and November must be maintained. If the normal flow of the Upper St. Lawrence

is reduced, an abnormal low discharge of the Ottawa River may result in record low levels in the harbor.

An increased discharge of the Niagara in winter may affect the flood heights during the spring break-up at and below Montreal. Large sums have been expended to guard against the consequences of these floods.

The future development of power, in a comprehensive way, on the St. Lawrence above Montreal will entail the control of the outflow of Lake Ontario, through the turbines of power plants and the sluice-gates of dams. It is clear that this control would be affected, perhaps favorably and perhaps unfavorably, by variations in the inflow into Lake Ontario through the regulation of the Niagara.

In short, many thousands of citizens of the United States and Canada, extending from Detroit, Mich., to Quebec, Que., have based their industry and their mode of existence, to varying degree, on the regimen of the Niagara as now established by Nature. The effect of any change must be considered before a scheme for regulation can be accepted by the two Governments concerned. If the direct benefits prove large and certain, a way will eventually be found to overcome the resistance of those who will be, or fancy they may be, injured to some degree directly or indirectly. If, on the other hand, the direct benefits are small, and realizable by other means at a cost commensurate with the cost of regulation, then it is evident that widespread indirect disadvantages will throw the balance against regulation.

### An Error of Viewpoint

A misconception exists as to the extent of the improvement in lake levels that might be accomplished by regulating works. The diversion of the Chicago Sanitary District may be placed at 8 500 cu. ft. per sec., that through the Welland Canal (Niagara River) at 3 000 cu. ft. per sec., and the equivalent effective diversion through the Black Rock Canal in the Niagara at 1 000 cu. ft. per sec., a total of 12 500 cu. ft. per sec. The result of these diversions is that the levels of Lake Erie are steadily 0.6 ft. lower than they would be had the diversions not been made. By constructing fixed works which will so contract the Upper Niagara River as to reduce its discharge capacity by 12 500 cu. ft. per sec. at all stages, the loss of 0.6 ft. can be restored without otherwise controlling the discharge. In other words, the low level of the lake, occurring subsequent to the diversions, would be raised by 0.6 ft. without increasing the high levels, which occurred prior to the diversions.

When, therefore, a system of regulating works is studied, and is found with the supplies of record, to raise the low levels of the lake by, say, 1.6 ft. without raising the high levels of record, it is evident that the 0.6 of the amount should not be credited to the regulation as such, but is the equivalent of a constant retardation which could equally well be secured by fixed works, at far less cost. The benefit attributable in such case to the installation of manually controlled gates is 1.0 ft. and not 1.6 ft.

### Official Studies

Apparently, the first serious proposal for the regulation of Lake Erie was made in 1900 by the Board on Deep Waterways, which had been specially

appointed to prepare plans and estimates for securing deep-draft navigation from the Great Lakes to New York Harbor. This Board proposed gates at the head of the Niagara River, which would hold Lake Erie at substantially the level of 574.7. This elevation is slightly higher than the maximum monthly mean level since 1860. It is only once in twenty years that the lake reaches within a foot of this elevation under the natural regimen of the Niagara River. It is very clear that so high a level would not now be tolerated.

Lake Erie can be held at a fixed level solely by discharging water from it as fast, and only as fast, as it is received. The discharge capacity of the Niagara, neglecting the retardation due to any gate piers, is 257 600 cu. ft. per sec. when Lake Erie is at Elevation 574.7. The supply for March and April, 1913 (296 000 and 324 000 cu. ft. per sec., respectively), would have raised the lake by nearly a foot with all regulating gates wide open. It is not possible to discharge water out of Lake Erie as fast as it may be received, unless the discharge capacity of the Niagara is greatly enlarged. In any event the lake can be held at substantially a fixed level only by greatly increasing the fluctuations of the discharge of the Niagara by an average of 50 000 cu. ft. per sec. each year and substantially reducing the ordinary low-water flow.

The question of the regulation of Lake Erie and of the Great Lakes, in general, was reviewed by the International Waterways Commission, a joint board of American and Canadian engineers. Its report, made in 1910, is a monumental study of the regimen of the Great Lakes. It pointed out the impracticability of regulating the outflow of Lake Erie so as to maintain a practically constant elevation of the lake, but presented a study of regulation based on the supplies of record, which was designed to hold Lake Erie within a range of 2.5 ft., as compared with the natural range, up to that time, of 3.8 ft. With the system proposed, there would have been an improvement of about 1 ft. in the ordinary low-water navigable depths on Lake Erie, about 0.3 ft. of which would have been due, however, to correcting the effects of diversions then existing. This improvement in the levels of Lake Erie would be at the cost of throttling the flow of the Niagara to its record minimum for a considerable part of the time, of increasing the fluctuations in Lake Ontario and in the St. Lawrence, and of lowering the minimum recorded level on Lake Ontario by about 4 in. In view of these counterbalancing injuries, the recommendation of the International Waterways Commission was adverse to the construction of regulating works in the Niagara River, or elsewhere.

### Other Proposals

Following this report various unofficial studies were made of the regulation of Lake Erie, some of which indicated that, with a suitable manipulation of the outflow, the disadvantages of the system studied by the International Waterways Commission could be overcome. The increasing demand for power, and the large amounts of power derivable from the head in the Niagara and St. Lawrence Rivers, pointed to the need for studying the manipulation of the levels of the lakes to develop the maximum useful storage, and the greatest steady outflow, in order to increase the potential output of primary power.

In 1919, Francis C. Shenehon, M. Am. Soc. C. E., made a report to the Chicago Sanitary District setting forth a scheme of regulation designed to equalize the summer flow of the Niagara River. As has been pointed out, the natural regimen affords an outflow which is ordinarily greatest in June and least in December. By retarding the flow after the danger of high water is past, it is possible to increase the autumn discharge. The results of the system studied indicated a gross gain of 19½ in. in the low levels of Lake Erie and of 12 in. in the high levels. The regulation, however, was based on an assumed diversion of 10 000 cu. ft. per sec. by the Chicago Sanitary District, and this diversion, with that of the Welland Canal and others, from Lake Erie would lower the lake by about 9 in. The effect of the proposed system of regulation would be, therefore, to raise the low levels by 10 in., and the mean levels by 3 in. more than could be effected by relatively inexpensive fixed works. The effect on the outflow of the Niagara is shown by the duration curves in Fig. 1.

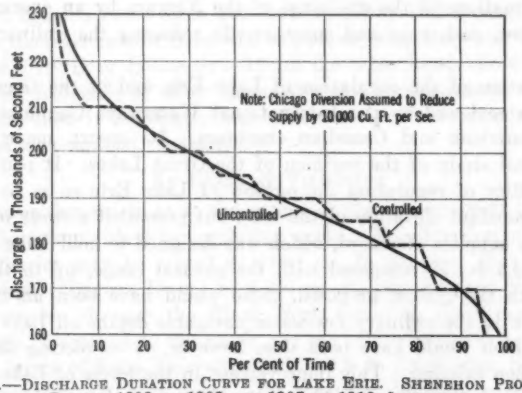

FIG. 1.—DISCHARGE DURATION CURVE FOR LAKE ERIE. SHENEHON PROPOSAL. PERIOD, 1893 TO 1902 AND 1907 TO 1916, INCLUSIVE.

In a paper[3] on the St. Lawrence Waterway before the Society, in 1924, Mr. Shenehon pointed out that the supply of water to the Great Lakes was sufficient to produce a steady outflow of 230 000 cu. ft. per sec., with a moderate annual hold-over storage. This is about 36 000 cu. ft. per sec. in excess of the present unrestricted minimum outflow.

In 1925 an Engineering Board of Review engaged by the Chicago Sanitary District prepared a scheme for the regulation of all the lakes, including Lake Erie. A careful review of the published computations and diagrams accompanying the report, and contained in a supplementary report of John R. Freeman, Past-President, Am. Soc. C. E., leads to the conclusion that the results of the system of regulation there considered would not differ substantially from those shown by the tentative study made by the Joint Board of Engineers on the St. Lawrence Waterway (presently to be discussed) so far

[3] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 444.

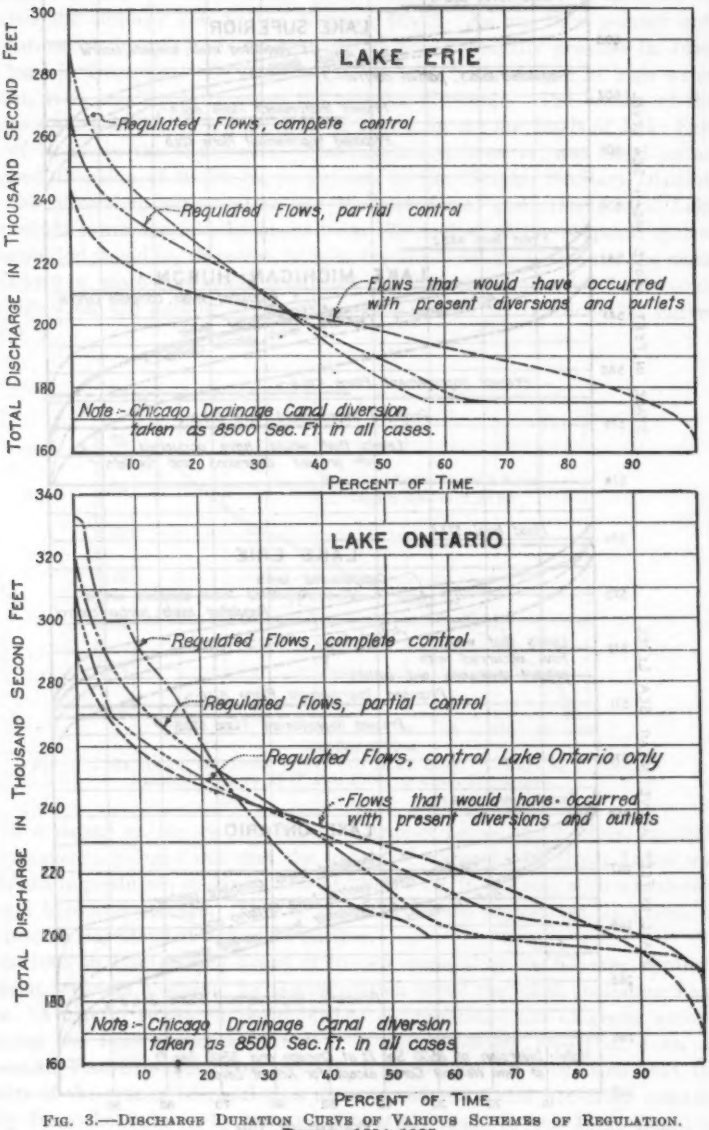

FIG. 3.—DISCHARGE DURATION CURVE OF VARIOUS SCHEMES OF REGULATION. PERIOD, 1894–1925.

at least as the fluctuations in the levels and discharges of the lakes are concerned.

The scheme of regulation proposed by the Engineering Board of Review contemplated raising the levels of the lakes about 2 ft. This suggestion appears to have been due, in part, to the fact that it would bring the high-water planes to the so-called high water of 1838, and, in part, to lack of available data on the injury that would result from such a rise in lake levels. It may be explained that the so-called high water of 1838 was a former datum plane on the Great Lakes, based, so far as some of the lakes are concerned, on incomplete data or no data as to the levels actually reached during that year. On Lake Superior the limiting elevation of the lake, under the rules for its regulation established by an international board in accordance with treaty requirements, is nearly a foot below the arbitrary datum of the high water of 1838.

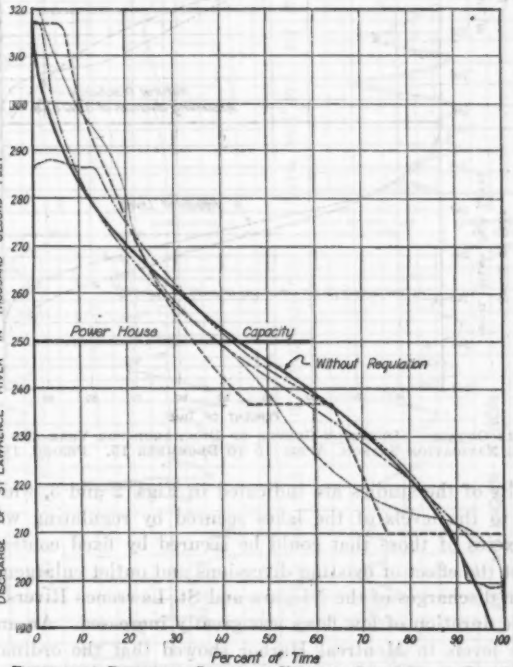

FIG. 4.—DISCHARGE DURATION CURVE OF VARIOUS SCHEMES OF REGULATION, LAKE ONTARIO ONLY.

## ST. LAWRENCE BOARD

The Joint Board of Engineers on the St. Lawrence Waterway, appointed by the Governments of the United States and Canada in 1924, made a detailed study of the possibilities of regulating the Great Lakes. This included a full investigation into the permissible high levels of the lakes, the maximum and

minimum discharges obtainable or permissible in the interconnecting rivers, and a revision of existing data on the water supply of the lakes since 1860, in the light of the latest evidence. With these data a tentative scheme of regulation, based on the budgeting of water between the lakes, was presented in detail. A modified program, based on a less comprehensive control of the outflow of Lake Huron, was also evolved.

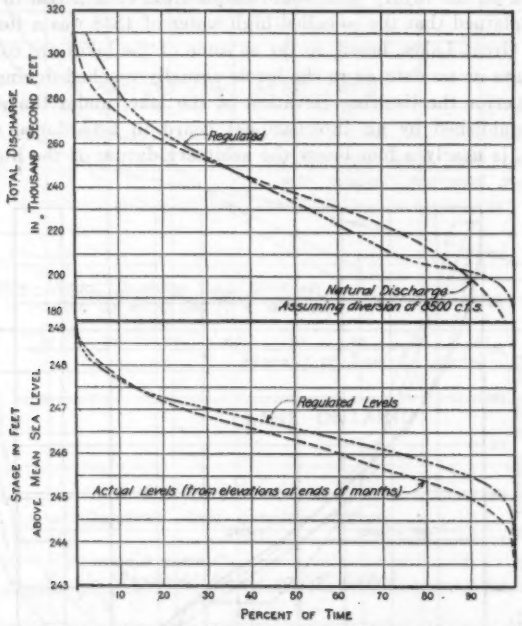

FIG. 5.—LAKE ONTARIO. DURATION CURVES OF DISCHARGE FOR YEAR AND LAKE LEVELS DURING NAVIGATION SEASON, APRIL 15 TO DECEMBER 15. PERIOD, 1861–1925.

The results of the studies are indicated in Figs. 2 and 3, which show that the benefits to the levels of the lakes secured by regulating works, are not greatly in excess of those that could be secured by fixed contractions which would correct the effect of existing diversions and outlet enlargements. While the minimum discharges of the Niagara and St. Lawrence Rivers were slightly increased, the duration of low flows was greatly increased. An analysis of the effect on the levels in Montreal Harbor showed that the ordinary low-water levels would be lowered by about a foot by the application of the program for comprehensive regulation. The benefits from regulation, when fully analyzed, were obviously such as to leave no ground for a recommendation that regulating works be constructed.

## CONCLUSIONS

The regulation of Lake Erie may be directed to reducing the fluctuation in its levels, or to altering the natural fluctuation of its outflow. It appears

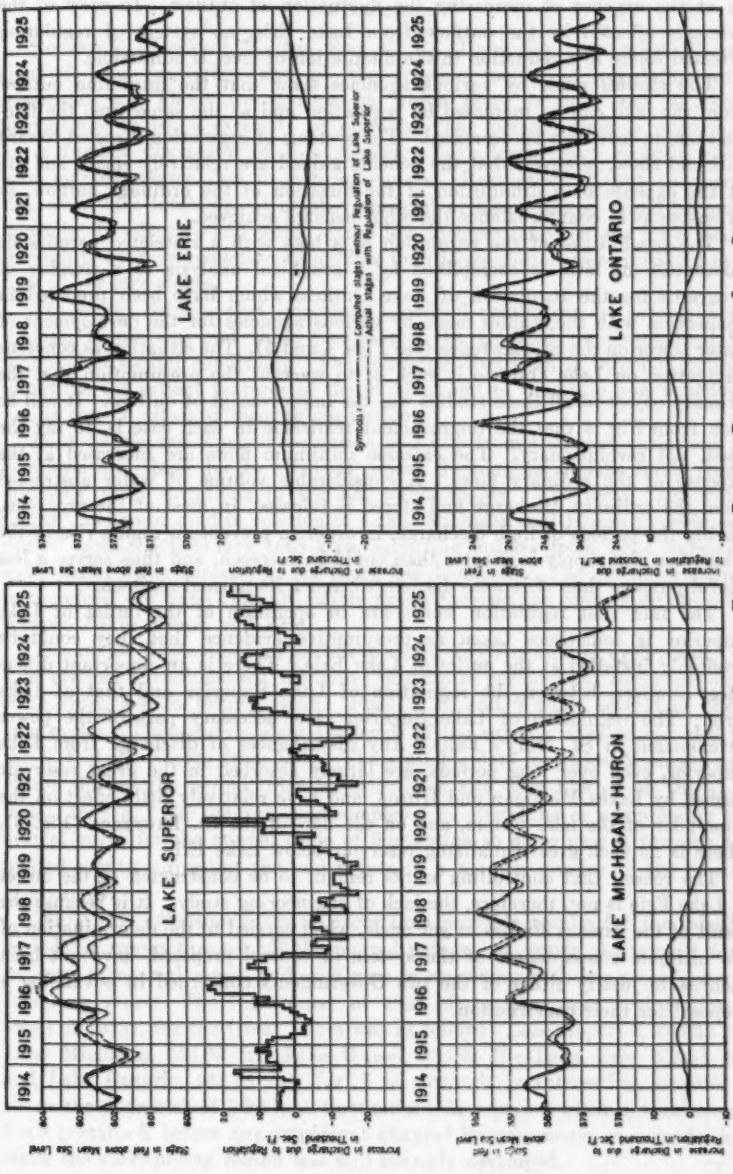

FIG. 6.—REGULATION OF THE GREAT LAKES. EFFECT OF PRESENT REGULATION OF LAKE SUPERIOR.

fundamental that a reduction in the fluctuation of the levels of a lake must be at the expense of increasing the fluctuation of outflow. In view of the interests affected by the outflow from Lake Erie, no system of regulation directed solely to a reduction in the fluctuation of level is admissible.

The studies made by various agencies show that the minimum outflow from the lake can be increased by regulation and at the same time the fluctuations in level can be decreased. The systems of regulation directed toward this end show, however, that the benefits gained are relatively small, and are at the expense of a diminution of the duration of the ordinary outflow, so extensive as to counterbalance the other benefits achieved.

The possibilities of the regulation of a lake with a restricted permissible fluctuation of level is exemplified by a graphical analysis of a number of programs for the regulation of Lake Ontario which have been prepared in connection with the studies made by various agencies for the development of water power on the St. Lawrence (see Figs. 4 and 5). The situation as concerns navigation on Lake Ontario is such as to warrant the presumption that the primary object in all these studies was the improvement of outflow. It will be seen from Fig. 4 that the improvement realizable in each case is, to say the least, not revolutionary. The extreme minimum flows are increased at the expense of the ordinary flows. A considerable volume of water abstracted from the ordinary discharge and stored is released, in most of the programs, during the periods of high discharge, in order to prevent an undue rise in the lake when the supply is greater than could be foreseen, and thus serves a less useful purpose than if it were discharged under its normal regimen.

The fact that regulation works are in operation at the outlet of Lake Superior is sometimes taken as presumptive evidence that they could be profitably installed at the outlet of Lake Erie. There is an important difference, however, between the regulation of Lake Superior and that of Lake Erie. The regulation of Lake Superior is a necessary part of the power development at St. Mary's Falls. Any disturbances of discharge from Lake Superior, even over long periods, are largely absorbed in the great reservoir formed by Lakes Michigan and Huron, and have relatively little effect on the remainder of the lake system, and on the flow of the St. Lawrence (Fig. 6). There is no such great equalizing reservoir below Lake Erie.

The reason that controlling works remain to be constructed at the outlet of Lake Erie is not, therefore, the lack of engineering study. It is because the result of the various studies as yet made, when carried to the determination of the ultimate consequences of the system of control proposed, have not been such as to justify either of the two Governments concerned in advancing a proposal for their construction.

# DISCUSSION

ROBERT E. HORTON,[4] M. AM. SOC. C. E.—There has been much discussion of lake regulation and of the relative merits of regulation and compensation. These are matters on which there is now, and is likely to continue to be, a diversity of opinion. The present time is opportune for a further discussion of this subject. Lake levels have recently risen to a marked degree due to natural causes. Regulation, if put in operation when lake levels are at or above normal or mean stages, would be more immediately effective and would cause less inconvenience on the lower lakes through temporary reduction in outflow than if regulation were initiated at a time of low lake stages.

The writer believes that important beneficial results can be accomplished through regulation, and these results may be attained unaccompanied by serious detrimental conditions. The following discussion is intended mainly to outline the salient features of the problem and to illustrate how beneficial results can be attained through regulation.

*Lake Levels and Their Fluctuations.*—Aside from transient variations in lake level and those due to artificial causes, fluctuations in lake levels result primarily from variations in the net water supply. The term, "net water supply", is herein used in relation to Lakes Michigan and Huron to designate run-off from the tributary land area, including outflow from Lake Superior, and yield of water surfaces of the lakes, less diversions. The net water supply is, therefore, the water that ultimately passes through the connecting channels between Lakes Huron and Erie.

The major fluctuations of lake levels are: (*a*) An annual cycle; and (*b*) long cyclical variations, not recurring in definite periods, but commonly covering from five to twenty years. Figs. 7, 8, and 9 show several of these long cycles. These curves show the levels of the various lakes as recorded by the U. S. Lake Survey from 1860. The available data for Lakes Michigan and Huron during the period, 1836 to 1859, have also been plotted on the same scale. In Fig. 7 the diagram was completed by stretching or compressing the normal curve for the annual cycle of fluctuation so as to pass it through the plotted points, adjusting the end points in a manner similar to the closing of a survey.

While this extension gives no more than probable results for the missing periods, it passes through all the plotted points, has nearly the normal form in years of normal range, and each year is consistent with the preceding and following years. The high water of 1838 above mean sea level (adjusted levels of 1903), for the Great Lakes was as follows: Lake Superior, 605.32 ft.; Lake Michigan, 584.69 ft.; Lake Huron, 584.69 ft.; Lake Erie, 575.11 ft.; and Lake Ontario, 248.98 ft. Fig. 7 is particularly interesting, because it shows the character of lake-level fluctuations in a period when natural conditions pertained, before any important channel improvements were made, and while the surrounding region was still sparsely developed.

[4] Cons. Hydr. Engr., Albany, N. Y.

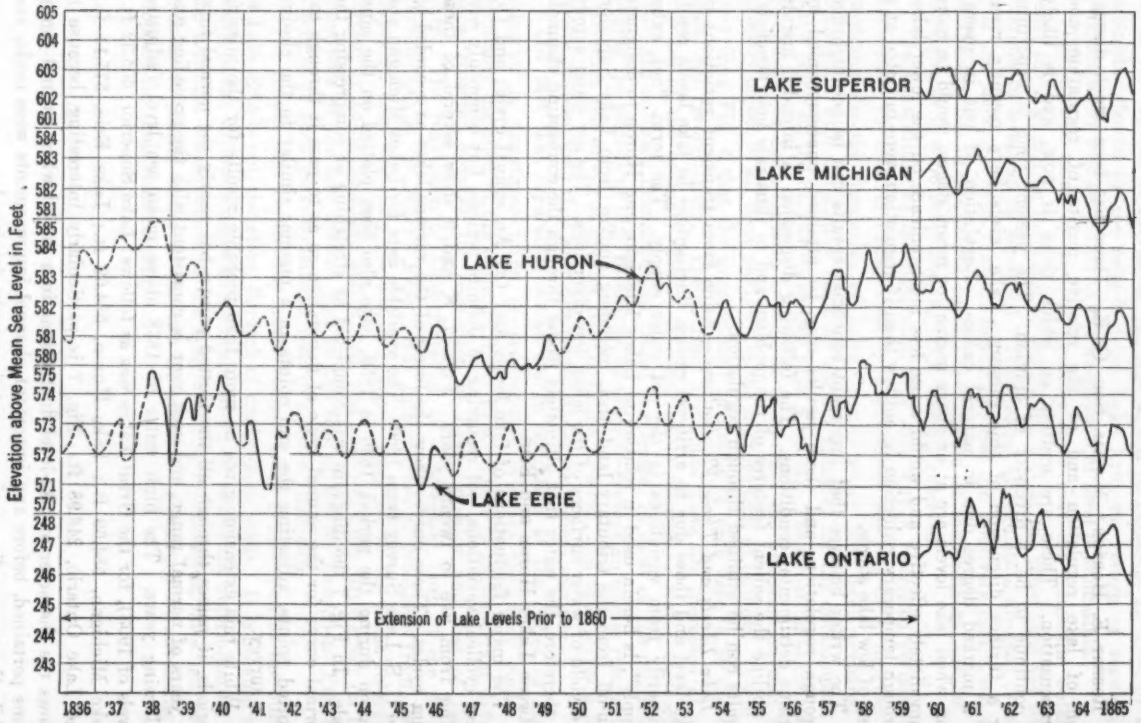

FIG. 7.—LAKE LEVEL RECORDS OF THE UNITED STATES LAKE SURVEY UP TO 1865, WITH EXTENSION BACKWARD FROM 1859 TO 1836.

FIG. 7.—LAKE LEVEL RECORDS OF THE UNITED STATES LAKE SURVEY UP TO 1865, WITH EXTENSION BACKWARD FROM 1859 TO 1836.

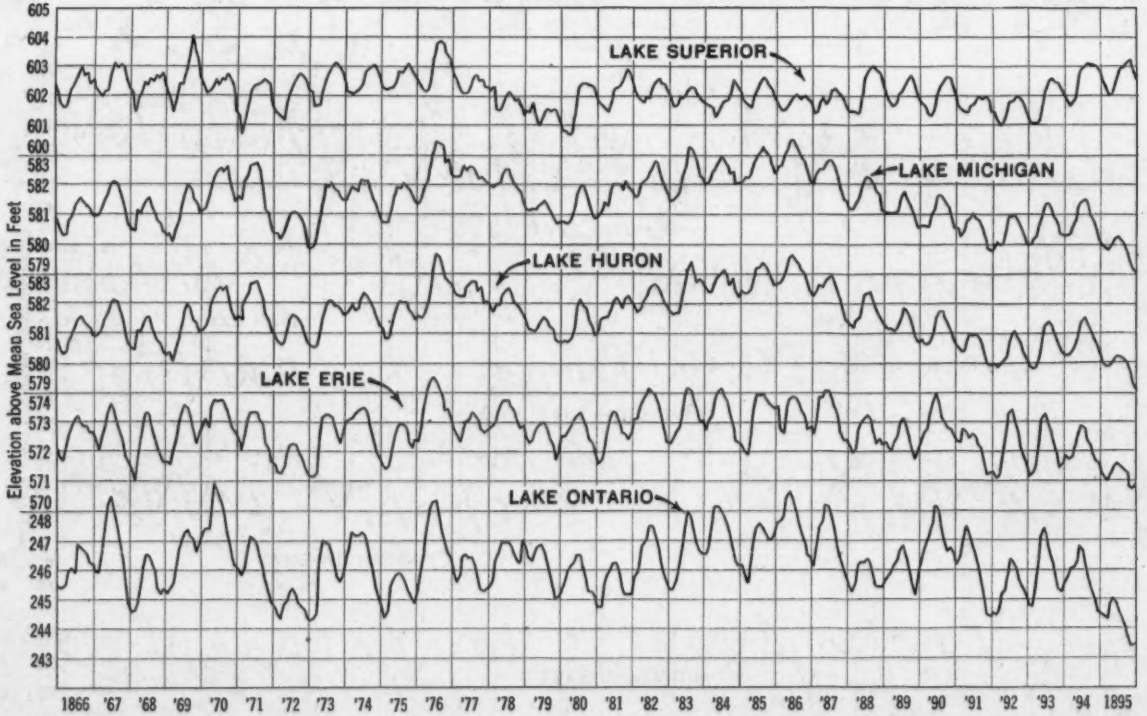

FIG. 8.—LAKE LEVEL RECORDS OF THE UNITED STATES LAKE SURVEY FROM 1866 TO 1895.

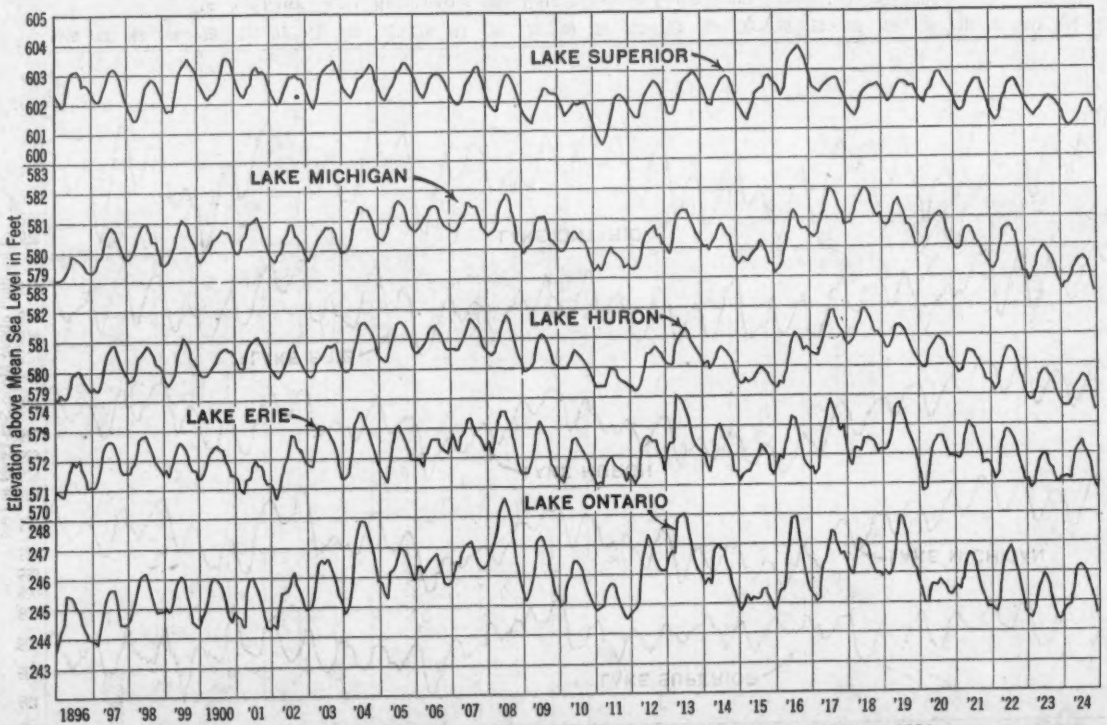

FIG. 9.—LAKE LEVEL RECORDS OF THE UNITED STATES LAKE SURVEY FROM 1896 TO 1924.

In 1847, Lake Huron fell to a level nearly as low as any in recent years. In 1852, the level of Lake Huron was almost as high as at any subsequent date. Two cycles of fluctuation are shown prior to 1860, similar in character to cycles which have subsequently occurred. That the lakes were higher in 1838 than at any time since seems certain. The elevation of the high-water plane of 1838 probably is not very accurately established.

Evaporation from the Great Lakes appears to be relatively more constant than rainfall. Since variation in rainfall is the principal cause of natural variation in lake levels over long periods, it is interesting to note that the irregular periodic character of long-cycle variations in lake levels is very similar to that for rainfall, as shown by the longest available records.

It is evident, therefore, that, unless there is a permanent change in rainfall, lake levels will tend to fluctuate in the future much as they have in the past, and the important conclusion may immediately be drawn that, aside from permanent changes due to artificial causes, the levels of the lakes, if left to themselves, will ultimately return from their present (1928) low stages to normal and even to extreme high stages, such, for example, as persisted in the Eighties.[5]

It may be noted that in the Eighties (see Fig. 8), Lake Michigan reached a maximum stage of 583 ft., or more, for four successive years, and during three of these years the lake remained above Elevation 583 for three or four months in each year.

The mean stage of Lakes Michigan and Huron in the maximum month of each of the years, 1924 to 1927, was about 579, while for the four years, 1883 to 1886, the mean of the maximum month was above 583, or more than 4 ft. higher than in the recent period. Similar relations hold for mean and minimum stages. Special attention is called to this matter because of its application to lake regulation and to the encroachment of structures on the lake margins. It appears certain that structures adjoining the lakes, placed at too low elevations in the belief that lake stages would remain substantially as at present, are bound to suffer serious consequences.

Of course, lake stages approaching those of the late Fifties or Eighties may not be realized fully because of the present lowering of lake levels as a result of diversions and channel improvements. These improvements have had a combined effect in lowering the mean levels of Lakes Michigan and Huron by an amount variously estimated as between the limits of 1 ft., or less, and 1½ ft., or more.

*Lake Regulations.*—Lake carriers commonly utilize the full available draft depth. Tonnage must be provided adequate to carry the commerce offered in periods of minimum as well as of maximum lake level.

Various desiderata of lake-level control include:

(*a*) Increase of the minimum depth in harbors and connecting channels.

(*b*) Reduction in fluctuation in lake levels, or the maintenance of a more equable navigable depth.

(*c*) Restoration of the depth lost in harbors and connecting channels through the combined effect of diversions and channel deepening.

[5] This statement (written in July, 1928), is confirmed by the upper lake stages of the summer of 1929.

FIG. 9.—LAKE LEVEL RECORDS OF THE UNITED STATES LAKE SURVEY FROM 1896 TO 1924.

There are three methods by which increased navigable depths may be obtained:

1.—By dredging the harbors and deepening the connecting channels.
2.—By compensation or fixed control in the outlet channels without regulation.
3.—By the construction of regulating works on the lake outlets.

The question may be asked: If increased navigable depth in connecting channels and harbors is required, why not provide it by dredging and excavation, as in the past? Other things remaining unchanged, dredging of course will provide increased depth only in the harbors dredged, while deepening of outlet channels—as already learned by experience—unless fully compensated, provides deeper water in the improved channel at the expense of lower levels in the tributary lake and, consequently, reduces the navigable depth in all harbors on the lake, the outlet of which is deepened.

Compensation consists in putting material back into an outlet channel outside the deepened navigable fairway with a view to preventing the increase in discharging capacity which would otherwise result from channel deepening. It amounts approximately to maintaining a constant cross-section, where the channel is deepened, by reducing the effective width sufficiently to offset the increased depth.

Fixed control structures are for the same purpose and operate in the same manner as compensation. Compensation in part has been carried out in the past in connection with improvement of the connecting channels between Lakes Huron and Erie.

Compensation seems very simple and effective, but it is subject to some serious defects as a remedy for reduced lake levels. Take, for illustration, a case such as that of the St. Clair River, where the discharge bears nearly a simple linear relation to the stage of the lake for moderate variations in lake level. Let it be assumed that compensation is made with reference to maintaining unchanged the mean stage at the outlet channel after the channel is deepened, and that this is accomplished by compensation outside the navigable waterway in such a manner that the relation of stage to discharge still remains linear. In Fig. 10 the line, $AB$, is the elevation of the original outlet control sill. The original relation between water surface elevation and discharge is shown by the line, $AH$. After deepening the channel to the elevation of the line, $DJ$, and reducing its width, the stage-discharge relation is as shown by the line, $DE$. The two discharge curves intersect at the point, $F$, corresponding to the mean stage, $M$, which is unchanged.

Table 1 is included to interpret the lines in Fig. 10. It shows that, while the navigable depth of the channel is increased at all stages, the range of fluctuation of lake levels is increased so that the maximum lake stages will be higher and the minimum stages lower than before the channel improvement takes place. In other words, the minimum navigable depth in all harbors on the tributary lake will be less than before the improvement, although the minimum depth in the outlet channel will be increased. This is due to the fact that, as a result of the compensation, the water level through the improved channel is not reduced as much as the channel itself is deepened.

Of course, compensation need not be made with reference to the mean stage. It can be made, for example, to preserve the minimum stage of the lake unchanged. In that case, however, there will be a larger increase in maximum stages than in the example just given. In general, channel improvement with compensation or fixed-outlet control alone will be found to operate to advantage in some respects and to a disadvantage in others. This is because compensation can only maintain the channel-discharging capacity unchanged at one particular stage.

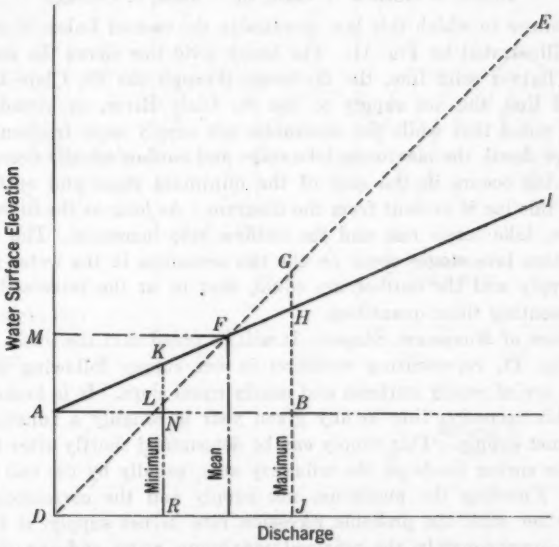

FIG. 10.—EFFECT OF CHANNEL DEEPENING AT LAKE OUTLET CONTROL POINT WITH "COMPENSATION" THROUGH REDUCTION IN WIDTH SO AS TO MAINTAIN PERMANENT MEAN LAKE STAGE UNCHANGED.

While a certain increase in maximum lake stages in the lower lakes over those pertaining in recent years should and undoubtedly can be tolerated, a decrease rather than an increase in range of fluctuation of the lake levels is desirable. Only thereby can the mean and minimum lake stages and navigable depth be increased without the certainty that at some future time the lakes will rise to objectionable heights.

TABLE 1.—EFFECT OF IMPROVEMENTS ON LAKE LEVELS.

| Lake level. | Before improvement. | After improvement. | Increase, or decrease. |
|---|---|---|---|
| Mean stage | *M* | *M* | ..... |
| Stage at maximum discharge | *H* | *G* | Increase, *GH* |
| Depth at maximum discharge | *HB* | *GJ* | Increased |
| Stage at minimum discharge | *K* | *L* | Decrease, *KL* |
| Depth at minimum discharge | *KN* | *LR* | Increased |

In contradistinction to compensation, or simple control, lake regulation consists in placing permanent structures below its outlet so that the water can be held back or released at will and both the lake levels and outflow can be controlled artificially to some degree. The ideal of constant lake levels at a moderately high stage with constant outflow rate is obviously unattainable.

The regimen of lake levels and outflow is controlled by the operation of the general law that applies to storage of all kinds, as follows:

$$\text{Inflow} = \text{Outflow} + \text{Gain, or} - \text{Loss, of Storage}$$

The manner in which this law operates in the case of Lakes Michigan and Huron is illustrated by Fig. 11. The heavy solid line shows the stage of the lakes, the lighter solid line, the discharge through the St. Clair River, and the dashed line, the net supply to the St. Clair River, as already defined. It will be noted that while the maximum net supply most frequently occurs in March or April, the maximum lake stage and outflow usually occur in July. A similar lag occurs in the case of the minimum stage and outflow. The reason for this lag is evident from the diagram. As long as the inflow exceeds the outflow, lake levels rise and the outflow rate increases. The maximum and minimum lake stages occur on the two occasions in the water-year when the net supply and the outflow are equal, that is, at the intersection of the lines representing these quantities.

*Prediction of Maximum Stages.*—It will be noted that the lines, *AA'*, *BB'*, etc., on Fig. 11, representing recession in net supply following the spring maximum, are of nearly uniform and nearly equal slope. It is found that the slope of this recession line in any given year is roughly a function of the maximum net supply. This supply can be determined shortly after the occurrence of the spring floods on the tributary area, usually by the end of March or April. Knowing the maximum net supply and the corresponding lake stage, together with the probable recession rate in net supply, it is possible to predict approximately the seasonal maximum stage and the date of its occurrence from two to four months in advance. This fact may prove to be of value in the operation of any plan of lake regulation, since it makes it possible to determine in advance when an abnormally high maximum stage is likely to occur. It is then also possible to begin at least two months in advance to slice off the crest of the maximum by discharging the excess water. These steps facilitate the operation of regulating works in such manner as to increase the minimum stages of the lakes without either increasing the maximum stage or reducing the outflow during the minimum period.

*The Use of the Storage Schedule.*—In the utilization of storage reservoirs in conjunction with power developments it is commonly desired to maintain a flow at all times at least equal to a predetermined minimum for the production of firm power. This result alone can be accomplished by keeping the reservoir always as nearly full as the draft requirements will permit. This method of operation is, however, generally wasteful of water. In addition to firm power, it is also often desirable to produce secondary power and to keep as much reservoir capacity available for flood control as power requirements permit.

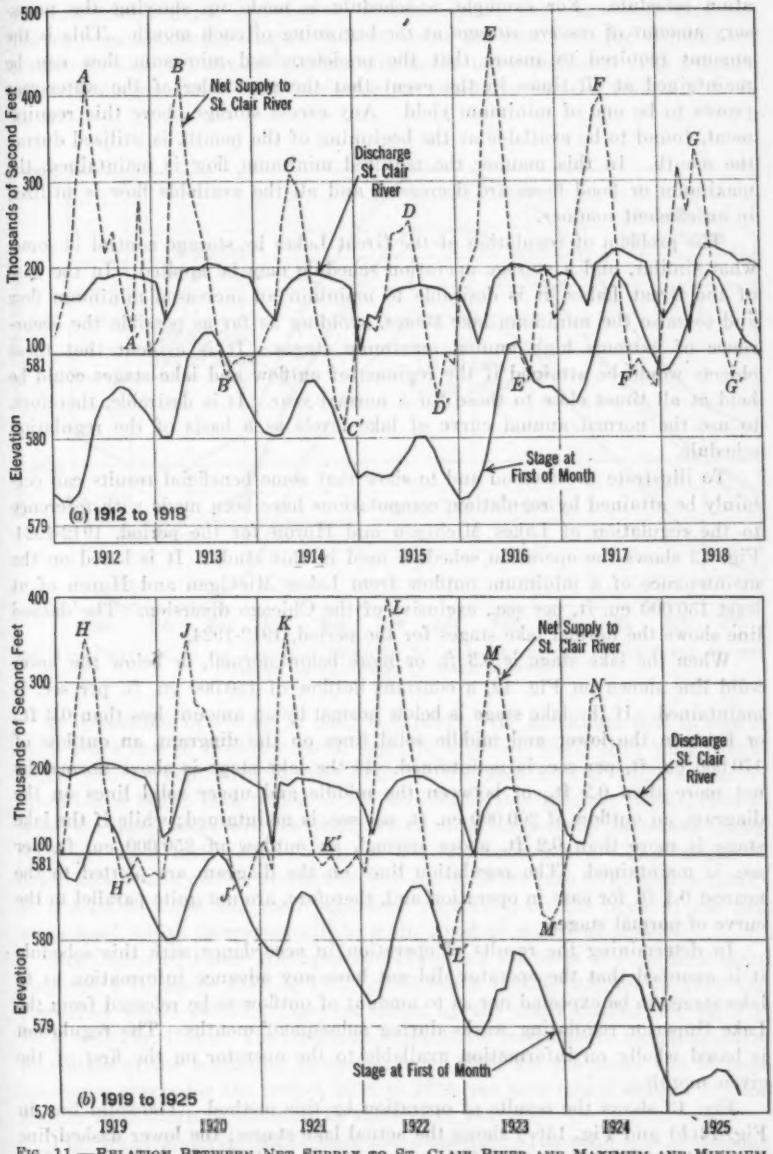

FIG. 11.—RELATION BETWEEN NET SUPPLY TO ST. CLAIR RIVER AND MAXIMUM AND MINIMUM ANNUAL STAGE AND DISCHARGE OF LAKES MICHIGAN AND HURON.

These combined functions are best served by the use of a storage operation schedule. For example, a schedule is made up showing the necessary amount of reserve storage at the beginning of each month. This is the amount required to insure that the predetermined minimum flow can be maintained at all times in the event that the remainder of the water-year proves to be one of minimum yield. Any excess storage above this requirement, found to be available at the beginning of the month, is utilized during the month. In this manner the required minimum flow is maintained, the maximum or flood flows are decreased, and all the available flow is utilized in an efficient manner.

The problem of regulation of the Great Lakes by storage control is somewhat similar, and a storage operation schedule may be applied. In the case of the Great Lakes, it is desirable to maintain an increased minimum flow and to raise the minimum lake stages, avoiding as far as possible the occurrence of extreme high annual maximum stages. It is evident that these objects would be attained if the regimen of outflow and lake stages could be held at all times close to those for a normal year. It is desirable, therefore, to use the normal annual curve of lake levels as a basis of the regulation schedule.

To illustrate the method and to show that some beneficial results can certainly be attained by regulation, computations have been made with reference to the regulation of Lakes Michigan and Huron for the period, 1912-1924. Fig. 12 shows the operation schedule used in this study. It is based on the maintenance of a minimum outflow from Lakes Michigan and Huron of at least 150 000 cu. ft. per sec., exclusive of the Chicago diversion. The dashed line shows the normal lake stages for the period, 1912-1924.

When the lake stage is 0.3 ft. or more below normal, or below the lower solid line shown on Fig. 12, a constant outflow of 150 000 cu. ft. per sec. is maintained. If the lake stage is below normal by an amount less than 0.3 ft., or between the lower and middle solid lines on the diagram, an outflow of 170 000 cu. ft. per sec. is maintained. If the lake stage is above normal by not more than 0.2 ft., or between the middle and upper solid lines on the diagram, an outflow of 200 000 cu. ft. per sec. is maintained; while if the lake stage is more than 0.2 ft. above normal, an outflow of 250 000 cu. ft. per sec. is maintained. The regulation lines on the diagram are plotted to the nearest 0.1 ft. for ease in operation and, therefore, are not quite parallel to the curve of normal stages.

In determining the results of operation in accordance with this schedule it is assumed that the operator did not have any advance information as to lake stages to be expected nor as to amount of outflow to be released from the Lake Superior regulating works during subsequent months. The regulation is based wholly on information available to the operator on the first of the given month.

Fig. 13 shows the results of operation by this method. The solid line in Fig. 13(*b*) and Fig. 13(*e*) shows the actual lake stages; the lower dashed line shows the regulated stages if the regulation had begun in January, 1912, without any attempt to boost the mean stage. It will be noted that the

extreme minimum stage in the period covered is raised 0.35 ft. above the unregulated minimum, and that the annual minima are much more uniform. The extreme maximum stage is 0.65 ft. below the maximum for unregulated conditions, and the annual maxima are much more uniform. The extreme range of fluctuation of lake levels for the period is reduced from 3.3 ft. to 2.3 ft.

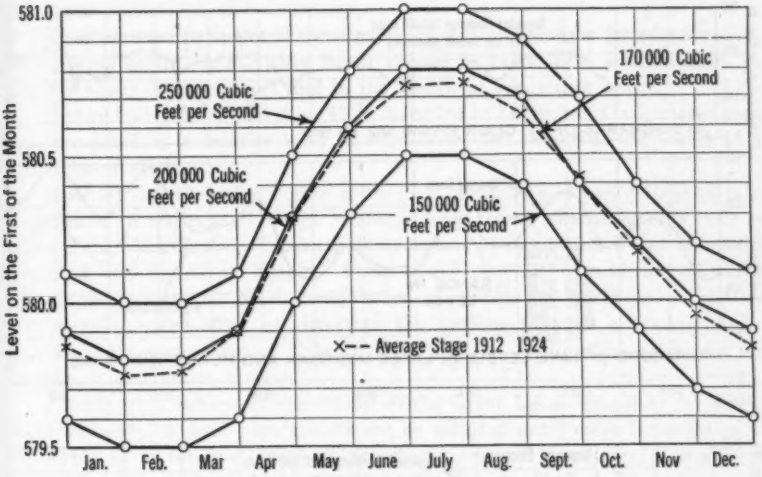

FIG. 12.—OUTFLOW TO BE RELEASED THROUGH ST. CLAIR RIVER FOR GIVEN STAGE OF THE LAKES ON THE FIRST OF EACH MONTH.

It is possible, of course, to hold back part of the maximum flow in one or more years and to raise the mean stage to a chosen level, after which regulation can be continued on the basis of the new normal stage curve. If operation is begun in a period of low lake levels and deficient supply, then to boost the mean stage will inevitably result in a temporarily decreased supply to Lakes Erie and Ontario and the St. Lawrence River. This might be objectionable and can be avoided by waiting until the lake levels rise naturally to a suitable stage and then beginning regulation on the basis of the new mean level, which thereafter will be maintained as closely as possible.

Regulation of Lakes Michigan and Huron on the basis of an annual mean stage of 1 ft. above that of 1912, could begin in this manner in 1918 and thereafter would provide stages as shown by the upper dashed line on Fig. 13(*b*) and Fig. 13(*e*). The maximum stage is not raised above the unregulated maximum at the beginning of operation in 1918, but the mean and extreme minimum stages for the period, 1918 to 1924, are both raised about 1 ft., and similar results can be obtained in subsequent years.

Fig. 13(*a*) and Fig. 13(*d*) show the discharge. The solid line is without, and the dashed line with, regulation. It will be noted that the minimum

outflow is increased materially for a period of several months in nearly every year. Two objections may be made to regulation in the manner described:

1.—That the full apparent increase in minimum discharge may not be realized because of ice obstruction in the outlet channel.

2.—That the maximum outflow rates are increased materially at times over those pertaining for the same lake stages with unregulated outflow.

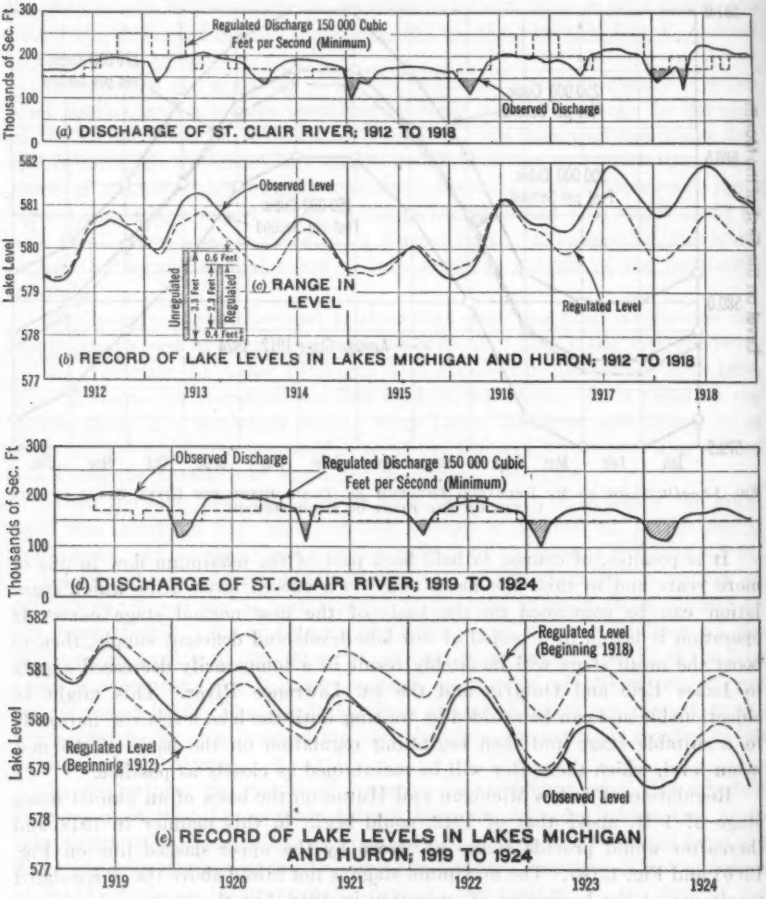

FIG. 13.—OPERATION OF REGULATING WORKS.

As to the first objection, it appears probable that the maintenance of higher lake stages will tend to reduce ice gorge formations. The successful use of thermite in breaking up icebergs suggests that it may be possible to accomplish more in the control of ice gorges than has been done in the past.

It is true that more water is discharged at times than would be discharged at the same lake stages with unregulated outflow. This condition undoubtedly could be mitigated to some extent by closer regulation, say, on a weekly instead of a monthly basis, by the use of maximum stage predictions made two or three months in advance, in some manner similar to that already described, and by the use of advance information as to the quantity of water expected to be released from the regulating works on the outlet of Lake Superior.

Some increase in outlet channel capacity will probably be found necessary, or at least desirable, and this factor should be taken into consideration in further study of the subject and in the design of regulating works.

It may be repeated that Fig. 13 is intended to be mainly illustrative; it is not presented as a definite basis of regulation, but rather as the result of a preliminary study.

Much of the discussion herein given as to methods and possibilities of lake regulation in the case of Lakes Michigan and Huron applies equally well to Lake Erie. Regulation of Lake Erie by means of regulating works above the crest of the rapids at Niagara Falls would provide, in addition to other advantages, means for diurnal regulation of outflow for power use as well as temporarily withholding or diverting the outflow in such a manner as to facilitate the restoration of Niagara Falls and the amelioration or prevention of future destructive erosion.

Finally, this subject of regulation of the Great Lakes should by no means be dismissed. A final plan should not be adopted until more information is available as to feasible limits of lake stages, or until more careful study has been given to the hydrologic and hydraulic aspects of the subject as well as its commercial and navigational aspects.

LYNN L. DAVIS,[6] M. AM. SOC. C. E.—The author has presented a most excellent summary of the various studies that have been made on this subject, and has very ably set forth the difficulties attendant on the solution of the problem. The speaker desires to give some facts concerning the importance of the commerce on the Great Lakes, and of the growing commerce on the Niagara River, because he considers that commerce is entitled to first consideration in a study of lake regulation. A few facts relating to the hydraulics of the Niagara River are also included.

*Commerce of the Great Lakes.*—The general public and most engineers have little conception of the extent of this industry and its tremendous and far-reaching effect on the life of the Nation. The latest published statistics of the commerce of the United States is for the season of 1926, and they show that the Great Lakes tonnage comprised more than 25% of all the waterborne tonnage handled in and on the United States ports and waterways. It was three times the Pacific Coast traffic; two and one-half times the Gulf Coast traffic; and more than two-thirds the Atlantic Coast traffic. It was larger than the tonnage handled on all the rivers and other inland waterways in the United States. Its relative importance to all other inland waterway

[6] Prin. Civ. Engr., U. S. Engr. Office, Buffalo, N. Y.

traffic is not correctly represented by the tonnage because the length of haul is much greater on the lakes. Of a total ton-mileage of more than 99 500 000 000 for all inland traffic, that on the Great Lakes consisted of more than 90 000 000 000 and all others of 9 500 000 000, or a ratio of nearly 10 to 1. This does not include the foreign traffic on the lakes, which constitutes more than 12% of the total lake traffic. These inland waterways consist of the rivers, canals, and connecting channels and the Great Lakes System.

The bulk of the freight carried on the Great Lakes consists of articles fundamental to the industrial life of the Nation and of foodstuffs for man and beast. In 1926, about 372 000 000 bushels of grain, 10 000 000 bbl. of flour, 60 000 000 tons of iron ore, and 14 000 000 tons of coal, passed through the Sault Ste. Marie Canals. Of the total freight tonnage carried on the Great Lakes, iron ore and its manufactured products constituted about 50%; coal, 26%; stone, 11%; grain and its products, 5½%; sand and gravel, 3%; and miscellaneous, 4½ per cent. About 98% of the iron ore handled in the ports of the United States is carried on the Great Lakes.

Duluth-Superior (Minn.-Wis.), Harbor, situated at the head of Lake Superior, is the second largest port in the United States. It received and shipped more than 53 000 000 tons of freight in 1926, which is surpassed only by New York, N. Y. The third port, Philadelphia, Pa., had a tonnage only a little more than one-half that of Duluth.

As has been stated by Colonel Pillsbury, the navigation interests are highly organized and will take advantage of every available inch of draft. It has been estimated that every such additional inch is worth $500 000 per season to the lake shippers. It is apparent, therefore, that a system of regulation that would increase the available depth 6 in. would be worth $3 000 000, and it is reasonable to assume that a large part of this saving would accrue to the producer and consumer.

*Commerce on the Niagara River.*—The average tonnage of freight carried on the Niagara River for the years 1924, 1925, and 1926, was about 3 333 000, which is about double what it was in 1914, when the Black Rock Ship Canal was opened to traffic. This ship canal is about 3.5 miles long and was built to provide safe navigation for the largest lake freighter around the very swift and shallow rapids at the head of the Niagara River. It displaced the section of the old Erie Canal that skirted the east bank of the river at this point, and now carries all the Buffalo traffic of the New York State Barge Canal. The present traffic in the Black Rock Ship Canal consists of nearly 50% Barge Canal traffic, which requires only 12 ft. of water. Less than 25% of the traffic utilizes the full available depth of about 19 ft.

The development of the deep-water pool in the river between Buffalo and Tonawanda, N. Y., as additional harbor space for Buffalo has been advocated, and such improvement has many points of merit. If the Black Rock Ship Canal were widened to not less than 300 ft. in the canal section and 400 ft. in open river to the full depth of the other connecting channel in the Great Lakes System, and if the mainland and Grand Island sides of this reach of the river were provided with adequate railroad service, the speaker believes that this frontage would develop rapidly.

It would be especially adapted to the winter grain-storage business which has recently developed in Buffalo Harbor. It is not unusual to have from fifty to one hundred of the largest freighters on the lakes storing grain in Buffalo Harbor during the winter. The grain is unloaded as required for rail shipment to Atlantic Coast harbors or to mills. This necessitates the service of several powerful ice-breaking tugs during the entire winter to move these vessels to and from the elevators. If this business could be transferred to the Niagara River there would be little interference from ice, because the river never freezes over and there is usually little floating ice from Lake Erie, except during from four to five weeks in the spring when the lake ice is broken up, but by that time most of the grain has been unloaded.

The prospects of the extension of the deep-water channel from Tonawanda to the Falls in the near future is not bright, because of the extremely high cost of the work due to the prevalence of solid rock. Such a channel would also require compensating works to prevent a considerable lowering of the river and lake. The cost of such an extension would be greater than all that has been spent to date by the Federal Government on Buffalo Harbor and Niagara River, and the most favorable estimates of probable future tonnage through such a waterway is less than 3% of the present tonnage in Buffalo Harbor.

In view, therefore, of the vast investment of money and effort in the navigation industry on the Great Lakes and the rapidly growing importance of the Niagara River commerce, their interests must enter in a very large measure into the final determination of method and amount of regulation or compensation.

*Hydraulics of the Niagara River.*—The speaker does not know of any data giving the levels of Lake Erie or Niagara River previous to the placing of artificial works in the head of the river in 1823-25, when the Erie Canal was built. This work consisted of closing the part of the river that flowed between Squaw Island and the mainland. Three structures were built: A dam; a dike along the east bank of that island from the dam to the head of the island; and a pier, which is virtually a dam, from thence to the head of the river, a distance of about 2½ miles, terminating on Bird Island, a rocky reef that was and is submerged during periods of high water. It was subsequently extended easterly about 3 100 ft. to increase the size of the harbor.

No data are available to determine how much this restriction raised the level of the water in Lake Erie, but it must have been at least 0.3 ft. and it may have been as much as 1.0 ft.

The original improvement of the Niagara River for lake navigation consisted of cutting a channel 400 ft. wide and 16 ft. deep through the reef at the head of the river. The cut consisted principally of the removal of portions of shoal spots on the reef and, while it must have caused a slight lowering, the total was probably not more than a fraction of an inch. Recent channel improvements between Black Rock Lock and Tonawanda have undoubtedly also resulted in a slight lowering of Lake Erie, but the sum total lake lowering from all channel improvements in Niagara River is less than 1 in.

For many years sand and gravel have been dredged from the river for commercial use. Most of this material was removed from a section about 4 miles long, extending down stream from the head of Squaw Island, or from 3 to 7 miles from the head of the river. No record of the total quantity dredged is available, but it must have been more than 10 000 000 cu. yd. About one-fourth of Squaw Island and three-fourths of Strawberry Island have been removed.

From studies of the effect of this dredging, made in 1926, it was estimated that the lake was lowered 0.3 ft. and the river at the foot of Squaw Island, 0.5 ft. All permits for dredging in the Niagara River were canceled as a result of these studies, and no such dredging has been allowed in the river since August, 1926.

The effect of all the diversions and of artificial changes in the Niagara River, on the level of Lake Erie, is shown in Table 2.

The levels in the river would not be affected in the same manner by the diversions listed in Table 2. All diversions made above the head of the river would affect the level in the Grass Island Pool at Niagara Falls slightly less than 50% as much as Lake Erie. For instance, the first two diversions in Table 2 would lower that pool only about 0.3 ft.; the third would have no appreciable effect because all the water is returned to the river; the fourth would have about the same effect on the pool as on Lake Erie; the fifth would lower the pool seven or eight times as much as the lake; and the sixth, the gravel dredging, would affect the pool level only slightly.

TABLE 2.—LOWERING OF LAKE ERIE DUE TO ARTIFICIAL CHANGES.

| Diversion of water by: | Lowering, in feet. |
|---|---|
| Chicago Drainage Canal | 0.41 |
| Welland Canal | 0.21 |
| Black Rock Canal | 0.03 |
| New York State Barge Canal | 0.01 |
| Niagara Falls Power Companies | 0.06 |
| Sand-gravel excavation, Niagara River | 0.03 |
| | 1.02 |
| Probable compensation of Erie Canal structures built previous to 1825 | 0.32 |
| Net lowering | 0.70 |

It seems, therefore, that Nature has provided a very efficient regulating device in the natural channel of the Niagara River, whereby only about one-half the extreme fluctuations in Lake Erie are transmitted to the river at the Falls, or, with a rise in Lake Erie of 12 ft., which occasionally occurs, a corresponding rise of not more than 6 ft. takes place at the Falls. On the other hand, the frequent daily fluctuations in the level of the Grass Island Pool, due to the variation in the quantity of water used by the power companies, causes very little change in the current or river levels near the head of the Niagara River.

The studies made of lake and river regulation have thus far failed to reveal any safe method of improving on Nature; therefore, it seems that only such compensating works as are necessary to restore original conditions are justified at present.

The plan suggested by the St. Lawrence Waterway Joint Board of Engineers in its report dated November 16, 1926, seems entirely feasible; it is comparatively inexpensive and can be built gradually, observing the effect and modifying it until the desired results can be obtained.

This plan consists of the following:

(*a*) Four submerged weirs or sills extending across the deep portion of the waterway near its head, with their tops 13 ft. below the water surface, thereby forming no obstruction to shallow-draft vessels.

(*b*) A wall or dike extending parallel with the direction of the current in the river, near the westerly end of the submerged sills, with its top 4 ft. above water level.

(*c*) A weir, extending diagonally from the up-stream end of the wall or dike to the Canadian bank of the river, with its top at low water.

This diagonal weir would extend through comparatively shallow water and is designed to restrict materially the low-water discharge of the river, while permitting the full-width discharge at flood stages. It is estimated that these works would raise the level of Lake Erie about 0.7 ft., without greatly affecting the flow of the river after the new level in the lake is established.

It may also be found necessary to build compensating works in the river at or near the Grass Island Pool to balance the slightly less low-water flow that would result from the works constructed at the head of the river.

THERON M. RIPLEY,[7] M. AM. SOC. C. E.—This matter of lake regulation is based on the need of providing better water transportation facilities. Studies were started at least thirty-six years ago. The first report in the speaker's possession was issued in 1894, and numerous reports have been made since that time. The transportation interests are justified in demanding that something be done, even if it is no more than an admission that the engineers of the United States can give them no help in this matter.

The fact can be stated that compensation or regulation, or a combination of the two, can be made so as to help lake transportation, and the engineers and shippers along the Great Lakes should be able to create a public sentiment that would demand physical action and institute construction of the necessary works.

It is granted that the control of a storage reservoir having an area of more than 55 000 sq. miles, which is fed not only by its own water-shed, but by that of another reservoir containing 32 000 sq. miles, contains hydraulic problems not often encountered. Nevertheless, these problems have been studied, as previously stated, for more than thirty years, by some of the ablest engineers in this country and the basic principles and main features have been agreed upon. In the reports mentioned, it is stated that 0.1-ft. elevation on the lakes was

[7] Cons. Engr., Buffalo, N. Y.

worth $660 000 per year to the navigation interests. This statement has never been contradicted and must be assumed correct until disproved. Moreover, there seems to be little doubt of the ability to provide at least a foot more water in Lake Erie (with the corresponding increase in elevation of Lakes Huron and Michigan) by the construction of remedial works. The speaker cannot understand, why, with a probable value of more than $6 000 000 per year in sight, there should be any question about the advisability of constructing the works required. What is now needed is that these facts be brought to the attention of those in authority and that those interested demand construction at once.

E. W. LANE,[8] M. AM. SOC. C. E. (by letter).—The control of the lake levels is a most interesting problem. The writer worked on the study of the regulation of the Great Lake levels made by the Joint Board of Engineers for the St. Lawrence Waterway, which was under the immediate direction of Colonel Pillsbury. He entered upon these studies with a predilection for the improvement of the existing condition by the construction of regulation works for the benefit of navigation and power development. This seemed better than the compensation of the lake levels for diversions by placing fixed obstructions in the connecting streams. Such fixed obstructions would benefit navigation by increasing the navigable depths, but would be of no advantage in the development of water power.

As a result of the studies, the writer is convinced that the Joint Board of Engineers got to the bottom of the matter, and shares with the author the view that the benefits at the present time (1929) do not justify the cost of regulation works. Since this opinion was stated by the Board, the Supreme Court decision on the Chicago diversion, and the rapid rise of lake levels, have further strengthened the conclusion.

The studies made heretofore for the regulation of the Great Lakes have been with the view of improving the lake levels for navigation, or of causing an increased flow in the Niagara and St. Lawrence Rivers in low-water periods, or to accomplish both these results. Another benefit of regulation is possible, however, but so far as known, no studies have been made of the practicability of regulation for this end.

Within transmission distance of the St. Lawrence and Niagara water powers are many existing and possible hydro-electric developments on streams which have a large flow at certain seasons of the year and low flow at others. The outflow of the Great Lakes varies in much the same manner as these streams, but it might be feasible to use the lakes, particularly Erie and Ontario, to store water during the season when the other streams had an excess, and discharge from storage when they were low. By the interchange of power an equalization of supply might be secured which would be of sufficient value to justify the expense of control works. In fact, it seems probable that some such result may come about as a natural sequence of events. When the International Section of the river is developed, it will probably be by means of a single dam at the lower end. For some years after this is completed there will be a surplus of power and a market for at least part of it will be found in

[8] Research Engr., U. S. Bureau of Reclamation, Denver, Colo.

supplying existing hydro-electric systems with power during their low-flow periods.

As the demand for power approaches the capacity of the International Section an effort will be made to continue to supply power during the low-flow season, to the existing hydro-electric systems, for since the value of secondary power is much less than that of primary power, the value per kilowatt-hour of power which will combine with the secondary power and provide a continuous supply, is considerably greater than the value of primary power. With this condition of the power demand there will be an immediate return on an investment in regulation works; and because of the immense quantities involved, they may be economically justified, especially since Lake Ontario will be already controlled by the power plant in the International Section and control works for Lake Erie are comparatively inexpensive. Because of the rapid changes taking place in the electrical power field, one would be rash to predict anything so far ahead as this condition must necessarily be; but to state that regulation would never be feasible would be equally rash.

F. G. Ray,[9] M. Am. Soc. C. E. (by letter).—The regulation of the Great Lakes has been a subject of discussion for many years. At first glance it appears to be a simple engineering proposition. There are, however, opposing interests to be served and restricting conditions to be met which offer many complications. The author has clearly set forth the fundamental considerations in reaching a solution and his conclusions show what little betterment may be expected in attempting to improve upon the regulation that Nature has provided. Regulation is feasible as he has shown, but it must be kept within a narrow range to avoid unreasonable damage to those whose interests are diametrically opposed to the interests benefited. The net result is small as measured by the cost. The time may come when regulation is warranted, but in the writer's opinion that time has not yet arrived.

The subject is highly interesting and should commend itself to the study of hydraulic engineers. If regulation is ever to be adopted, every practicable plan should be conceived and considered in advance. Regulation of Lake Superior is now in successful operation. The program to be followed and the benefits to be derived with regulation of Lakes Erie and Ontario are matters for study, but the design and construction of regulating works for the Niagara and St. Lawrence Rivers offer no serious difficulties. Regulation of Lakes Michigan and Huron, however, is a more intricate problem. These lakes discharge through 90 miles of channel which carries a flow of 200 000 cu. ft. per sec., with an average slope of less than 0.1 ft. per mile. There is an immense traffic through this channel, which must not be seriously hampered by obstructions or largely increased velocities. These are conditions that must be met in regulating the two lakes in question.

In analyzing the practicability of regulating schemes it has been customary to test them by use of supply factors and lake levels of record since 1860. The plans discussed by Colonel Pillsbury were so tested by him up to 1925. The writer has extended the so-called partial regulation scheme for Lakes

[9] Prin. Engr., U. S. Lake Survey, Detroit, Mich.

Michigan, Huron, and Erie through to the end of 1929. It is interesting to note that the high-water peak which resulted in considerable damage on Lakes Michigan and Huron in 1929 would have been exceeded by 1 ft. and Lake Erie would have gone 3 in. above the highest previous level since 1860, if this particular plan had been in operation. Regulation projects based on supply factors now available are accordingly further restricted or subject to less favorable results.

The author has shown the effect of Lake Superior regulation on the levels of the several lakes from 1914 to 1925, inclusive. This study has also been extended to include 1929. It has been found that the maximum stage on Lake Superior in 1928 was about 7 in. below what the unregulated level would have been; also that the effect of the regulation on the maximum stages of Lakes Michigan, Huron, and Erie in 1929 was to raise each of these lakes slightly less than 2 in.

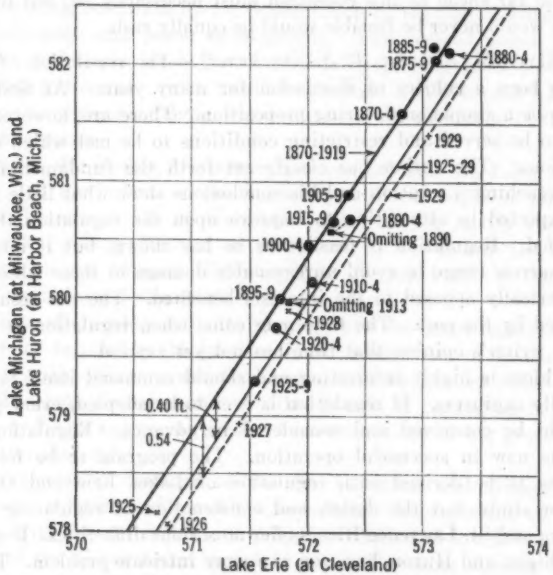

FIG. 14.—COMPARISON OF LEVELS IN LAKES MICHIGAN-HURON AND LAKE ERIE.

In proposals for compensating works in the outlets of the several lakes, it is usually considered that such works should be designed so as to compensate for all losses in lake level due to diversions and to changes in original capacity of outlet. The amount that Lake Erie has been lowered and the corresponding amount of compensation required in the Niagara River are known with little uncertainty. In the case of Lakes Michigan and Huron the effect of diversions are determined by means of measured increments of flow in the outlet. The possibility of changes in capacity of outlet and the lowering

effect on Lake Huron of channel enlargements in the St. Clair and Detroit Rivers, prior to the beginning of discharge measurements in 1899, cannot be determined by direct observation, except through comparison of past and present relation of levels on Lake Huron and Lake Erie. The period of relatively low water from 1890 to 1926 left considerable doubt as to the showing of such comparison. The high stages of 1929 have done much to strengthen the evidence.

Fig. 14 shows a comparison of lake levels by plotting 5-year means with the levels of Lakes Michigan and Huron as ordinates and the levels of Lake Erie as abscissas. The observed levels have been corrected for earth tilt to corresponding levels at the outlets. It will be noted that 5-year means from 1870 to 1919 show little departure from a straight-line relationship, except for the two groups, 1890-1894 and 1910-1914. The local supply to Lake Erie was notably excessive in 1913. Lake Erie levels in 1890 appear relatively high. The reason has not been investigated. When the two years, 1890 and 1913, are omitted, the levels for the remaining 48 years of the 50-year period are remarkably consistent, and show no evidence of change in relative height, the levels for 1925-1929, however, fall about 5 in. below the 1870-1919 line and the single years, 1926, 1927, and 1929, are about 6½ in. below this line. The 1929 levels are well up among those of early years. The evidence indicates that Lake Huron held its proper level until after 1919 and has been lowered since that time by about 6 in. This amount is subject, of course, to some error resulting from inequalities in local supply.

Soundings in the head of St. Clair River in 1925 showed a marked enlargement in cross-section due to gravel dredging in the vicinity of Point Edward and below. The amount of enlargement indicates a resultant lowering of about 4 in. on Lake Huron. Discharge measurements and analysis of slopes show the effect to be about 3½ in. The amount of lowering not accounted for by this enlargement is apparently not more than about 3 in. A continuation of high water on the lakes will afford safer and surer conclusions. However, in the writer's opinion, the effect on Lake Huron levels of channel improvement and other changes in the St. Clair and Detroit Rivers is now known quite definitely.

George B. Pillsbury, M. Am. Soc. C. E. (by letter).—This paper was prepared to introduce and invite discussion on lake regulation as affected by the Niagara River. In addition to the discussions presented, attention is invited the able treatment of the regulation of Lake Erie with reference to power, contained in the paper by Norman R. Gibson, M. Am. Soc. C. E., entitled "Niagara Power"[10] and in discussion[11] thereon by William Kelly, M. Am. Soc. C. E.

To the Engineering Profession at large, as well as to the general public, the feasibility and desirability of the regulation of the lakes appear axiomatic. The writer must confess that he approached the subject, some years ago, in a more than hopeful frame of mind. It is difficult to appreciate the extent

[10] See pp. 16 *et seq.*

[11] See p. 41.

to which widespread interests have adjusted themselves to the present regimen of the lakes and their outlets, and the extent to which injury, more or less weighty, would be created by even small changes in this regimen.

A feature of lake regulation also difficult of appreciation, which was brought out by Mr. Gibson,[12] is that a system of regulation by which the discharge increases uniformly with the elevation of the lake will afford the least volume of high discharge and the greatest volume of useful flow. This is the system of regulation afforded by the natural outlets. An examination of the results secured by Mr. Horton's suggested regulation of Lakes Michigan and Huron, in Fig. 13, shows that while the extreme low flow is increased, the ordinary flow is decreased for a much longer part of the time. The duration curve of Mr. Horton's regulated outflow would unquestionably take the same general form as that indicated for the regulated flows of Lakes Erie and Ontario in Fig. 3.

A third feature of regulation of the lakes, which is generally overlooked, is the limited discharge capacity of the outlets. In Mr. Horton's plan, it is proposed, for example, to discharge 250 000 cu. ft. per sec. from Lake Huron when the elevation of that lake is 580.2 ft. above sea level. Assuming that Lake Erie is even 9 ft. below Lake Huron, the St. Clair River can not discharge as much as 200 000 cu. ft. per sec. when Lake Huron is at this level. The enlargement necessary to increase the discharge capacity of the St. Clair River by 25% might well cost more than the deepening of all the channels and harbors of the lakes by an amount equivalent to the maximum benefits from any suggested system of regulation. It is to be recollected that the outlets to the lakes are now, and steadily have been, discharging water just as fast as they possibly can, but that at present the lakes are nevertheless higher than some would like. The cost of enlarging the outlets—all the way down to Montreal—to a degree sufficient to afford a comfortable margin for regulation, is one of the reefs on which proposals for regulation are shipwrecked.

Mr. Horton explains very clearly the theoretical objections to controlling works as a remedy to the causes of impaired lake levels. It is to be observed, however, that in Fig. 10, the lines, $A\,I$ and $D\,E$, when considered in their entirety as extending to the virtual sills of the outlet, are not right lines but are concave downward. In any practical application of compensating works, to correct the relatively small causes that have resulted in lowering the lakes, the two curves are so nearly parallel, in the region comprised between the range of lake levels, that the distances, $K\,L$ and $G\,H$, are inappreciable.

Especial attention may be invited to Mr. Ray's discussion, with which the author completely concurs. It is hoped that the interesting discussions that have been presented will afford further light on this moot engineering question.

# EXPERIMENTAL RESEARCH ON VIBRATION DAMPERS AND INSULATORS[1]

By Stephen E. Slocum,[2] M. Am. Soc. C. E.

With Discussion by Messrs. J. P. Den Hartog, Francis G. Tatnall, W. M. Dawley, and Stephen E. Slocum

Synopsis

The study of vibration insulation presented in what follows is an original research undertaken in connection with the general problem of preventing vibration in structures, as applied in particular to the terminal improvements of the Pennsylvania Railroad at Philadelphia, Pa., now (1928) under construction.

In order to study the transmission of vibration it was necessary to have two vibrating systems to act as transmitter and receiver, respectively. Each of these elastic systems had its own vibration characteristics. Moreover, the insulator placed between them was also elastic and resilient and, therefore, added a third vibrating element. Loads were also transmitted through this threefold composite system, which had a further effect in modifying the vibration characteristics.

It is a notable fact, however, that no practical solution has yet been found of the vibration characteristics of such a primary element as a simple beam of uniform cross-section under load. Simplifying assumptions, such as neglecting the mass of the beam, or assuming that it is unloaded, have always been found necessary to a mathematical solution, and these make the results of such analysis of little practical value.

Moreover, such experimental studies of vibration insulators as have appeared, have also been of a very special nature and so limited in scope as to warrant no general conclusions. It is evident, therefore, that the present

[1] Published in October, 1929, *Proceedings*.

[2] Cons. Engr., Ardmore, Pa.

study is of a somewhat pioneer nature in a difficult field of growing practical importance. It is believed that the essential features of the problem have been kept distinct, and that practical results have been brought to light concerning the general problem of vibration control.

---

## Vibration Control

The use of insulation for creating a short circuit in vibration in structures is only one phase of the complicated problem of vibration control. The general problem, whether considered in relation to structures or machinery, is a dynamic rather than a static one. Probably it is for this reason that greater progress toward a solution has been made in mechanical than in structural lines.

The general problem of vibration control may be classified under several heads. In the design of permanent machinery installations, such as lighting and power units in office buildings and apartments; batteries of looms, printing presses, or machine tools in shops and factories; marine installations; automotive and aircraft power plants, etc., the first step toward a solution consists in eliminating the unbalanced effects in rotating parts by means of dynamic balancing.

This alone, however, is in general only partly effective. In reciprocating machinery where the power fluctuates, it is of the utmost consequence to design parts affected by vibration so as to avoid critical speeds. In relation to building construction, critical speeds are those at which synchronous vibrations are set up in one or more members of the structure. When vibration is due to permanent installations, such synchronous vibrations may be avoided, as in machinery, by properly designing individual structural members, such as columns and girders.

The third general principle, applying particularly to structural work, consists in causing the vibration to become "short-circuited" by confining it to the region where it originates. For example, a machine may be mounted on a structure entirely independent of those adjacent to it; various types of insulation may be interposed between the structures; nodes may be artificially created at points of contact; or use may be made of existing nodes in the structure, the latter in particular being a very useful method in marine installations.

Mechanical insulators fall into two general classes: Those that are elastic and resilient, such as cork, felt, and rubber; and those that are almost or entirely lacking in these qualities, such as asbestos, lead, sand, and gravel. Properly speaking, there is no such thing as a vibration absorbent, since this implies dissipation of energy through internal work in the form of molecular friction, heat losses, etc. Resilient materials store up energy like a spring, and give out this energy again when released without appreciable loss; and the damping properties of non-resilient materials, such as sand and gravel, depend on destroying the rigidity, or interrupting the continuity, of otherwise rigid structures.

## Description of Apparatus

For the purpose of this study it was essential to have two elastic systems, one of which could be set in vibration mechanically and would serve as transmitter, while the other could be insulated from the first by the material under test, and would serve as receiver of such vibration as passed through the insulation. It was also considered essential to provide for a considerable range of loads on the test piece, and for varying the frequency of the forced vibration within practical limits. The general arrangement of the test apparatus designed to meet these requirements is shown in Fig. 1.

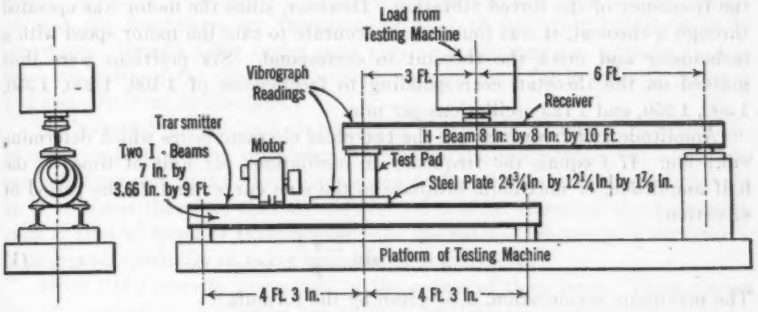

Fig. 1.—Arrangement of Testing Apparatus.

To secure the desired loading, and also a long platform on which to set up the test apparatus, a large testing machine, with a platform 20 ft. long, was chosen as a base for the experiments. The primary vibrating system, or transmitter, consisted of two 7-in., 15.3-lb., I-beams, 9 ft. long, mounted parallel to each other, and lengthwise of the platform of the testing machine. On this pair of I-beams, a 1-h.p. electric motor, with an unbalanced driving pulley, was clamped, to produce the forced vibration. At the center of the beams and adjacent to the motor a machined steel plate was clamped lengthwise to form a platform for the insulating material under test (Fig. 1). On this platform, beside the test pad, was placed the "vibrograph" by which the amplitude of the forced vibration was recorded.

The unbalanced effect on the driving pulley of the motor was obtained by removing one of the bolts by which the pulley was attached to the flange and replacing it with a longer one carrying a heavy nut at each end. The motor speed, or frequency of the forced vibration, was controlled by a rheostat giving a speed range from 1 100 to 1 725 rev. per min.

Directly over the transmitter, an 8-in. 31-lb., steel H-beam, 10 ft. long, was mounted so that one end was supported on the insulating material under test, and the other end blocked up on the platform of the testing machine. This H-beam constituted the secondary vibrating system, or receiver.

The load from the testing machine was applied to this H-beam through a spherical bearing-block. By this means both the static load and the dynamic vibration were transmitted in all cases through the insulating material under test.

### Vibrograph Records

The graph traced by the vibrograph was a simple sine or cosine curve, without harmonics, which represents the simplest possible type of vibration. Throughout the entire series of tests the ratio of amplification was 12; that is, the amplitude of the graph traced by the instrument was twelve times the amplitude of the actual vibration. As reproduced in this paper, the vibrographs are six times the actual scale of amplitude, or one-half the full size as traced.

The instrument has an auxiliary pen that traces a graph of known frequency, and this is used ordinarily as a base for determining, by comparison, the frequency of the forced vibration. However, since the motor was operated through a rheostat, it was found more accurate to rate the motor speed with a tachometer and mark the rheostat to correspond. Six positions were thus marked on the rheostat, corresponding to frequencies of 1 100, 1 200, 1 350, 1 500, 1 650, and 1 725 oscillations per min.

Amplitude and frequency are the two chief characteristics which determine vibration. If $f$ equals the frequency in oscillations per unit of time; $a$, the half amplitude, or maximum ordinate to the sine curve; and $T$, the period of vibration:

$$y = a \sin \frac{2 \pi t}{T} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The maximum acceleration, $\alpha$, is given by the formula:

$$\alpha = 4 \pi^2 f^2 a \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Since acceleration is the fundamental quantity of dynamics, the vibrograph records evidently determine fully the characteristics of the vibration.

The readings were taken by placing the instrument alternately on the test platform of the transmitter beside the test pad, and on the upper flange of the H-beam, or receiver, directly over its point of support on the test pad. In each position a graph was recorded at each of the six speeds to which the rheostat was calibrated. Each test at a given load, therefore, comprised two sets of six vibrograph records, or twelve graphs altogether.

Moreover, the tests covered a considerable range of loads. For materials like sand, gravel, lead, and asbestos, the test loads as measured on the scale-beam of the testing machine ranged from 300 to 24 000 lb., corresponding to a maximum unit intensity of loading on the test pad of 450 lb. per sq. in. In some cases this schedule required a total of ninety-six vibrograph records for one complete test. For corkboard and similar materials on which the load range was more limited, a complete test usually totaled forty-eight records.

The speed of the drum carrying the paper roll on which the graph was traced, was regulated by a governor which maintained the angular velocity constant. The linear speed of the paper passing under the pen, therefore, depended on the diameter of the roll. The graph thus appears more extended in some cases than in others, depending on the diameter of the paper roll when the record was taken. This does not affect the frequency, since the frequency was determined by calibrating the rheostat.

### Interpretation of Graphs

The test apparatus was assembled from commercial units, subject to the usual variations in uniformity of shape and loading actually met in practice.

The results are, therefore, more typical of actual conditions in engineering than would have been the case with apparatus of greater refinement, such as might be available in a physics laboratory.

If a single load or a single frequency had been adopted, doubtless the results would have shown a greater uniformity, but it is precisely this lack of uniformity that is met in practice. A train entering or leaving a terminal or subway station is subject to a continual variation in speed which often causes a severe vibration to appear at one instant and disappear the next. A live load passing over a structure also causes the load in any given member to vary within relatively wide limits. Such varying effects, due to continual change in load and frequency, are therefore essential to the study of vibration in structures. Graphs taken under such varying conditions also serve to disclose the complexity of the vibration problem and the need for systematic research and specialization in this field.

The so-called impact load in bridges is a dynamic effect due to vibration; it arises not only from unbalanced forces in the locomotive, but also from periodic forces set up by wheel loads succeeding each other at regular intervals. It is apparent therefore that the relation of load to vibration characteristics, such as critical speed or synchronism with the natural frequency of structures, is of great importance in many branches of engineering.

About 2 000 records were taken in the course of these tests. Those chosen for illustration in this paper are typical, and display certain characteristic properties of the material or loading.

It is evident on inspection that load has a marked effect in modifying vibration characteristics. Thus, Fig. 2(*a*) and Fig. 2(*b*), taken with the same unit load, exhibit similar characteristics; whereas Fig. 3(*a*) and Fig. 3(*b*), taken with the same insulating pads, but with a different unit load, show quite different characteristics. In Fig. 3, the motor speed is synchronized with the natural frequency of the transmitter.

Frequency has little effect on the damping properties of insulation—that is, on the percentage of amplitude damped out by the pad—except at critical points. The percentage of damping, however, depends very largely on the kind of insulation, or the material of which the pad is made, as will appear more fully later.

In interpreting the vibrographs, therefore, the effect of load, material, and frequency must be clearly distinguished in making comparisons.

## Corkboard Insulation

The insulating properties of any type of resilient pad is a function of its deflection under load. Experience has shown that in order to secure the best results in machinery insulation it is important to adjust the dimensions of the pad to the load and, also, to the speed of the machine, or frequency of vibration. Either the thickness of the pad may be changed, keeping the area constant; or the area may be altered, keeping the thickness constant. In either case, the deflection of the pad under load is affected, which is the chief quality on which its properties as a vibration damper depends.

Corkboard is widely used for vibration insulation, and is commercially standardized for this purpose as to density and dimensions. For test purposes

blocks of corkboard were used, 6 by 6 in. in area by 3 in. thick. They were of standard density equal to 0.319, which is equivalent to a unit weight of 1.66 lb. per board-ft. The compressibility of this material under load is given by the load-deflection curve shown in Fig. 4, plotted from test data obtained from one of these pads.

The corkboard blocks were piled up so as to give four thicknesses for vibration tests, namely, 3 in., 6 in., 9 in., and 12 in. Each pad was tested for a series of loads, and vibrographs were taken at six frequencies for each load. The results obtained with two of these thicknesses of corkboard pad under a unit load of 27 lb. per sq. in., are shown in Fig. 2.

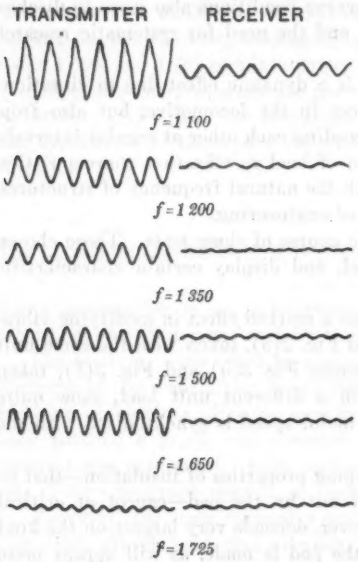

FIG. 2(a).—VIBROGRAPH OF CORKBOARD, 6 BY 6 BY 6 IN. (UNIT LOAD, 27 LB. PER SQ. IN.)

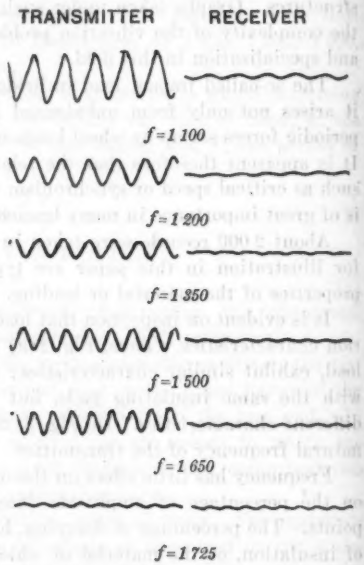

FIG. 2(b).—VIBROGRAPH OF CORKBOARD, 6 BY 6 BY 12 IN. (UNIT LOAD, 27 LB. PER SQ. IN.)

If $T$ denotes the amplitude of vibration of the transmitter, and $R$, the amplitude of vibration of the receiver, then $k = \frac{R}{T}$ may be assumed to indicate the amount of damping. With this notation, the percentage of amplitude of vibration damped out by the pad becomes $D = 100\ (1 - k)$. By scaling the amplitudes from the vibrographs and determining the damping percentage it is found that, for the first five frequencies, the damping percentage for a given depth of pad is practically constant. The average values of $D$ for these five frequencies are plotted in Fig. 5.

It is further evident from Fig. 2 that, at the highest frequency, namely, 1 725 oscillations per min., the amplitude of vibration of the transmitter

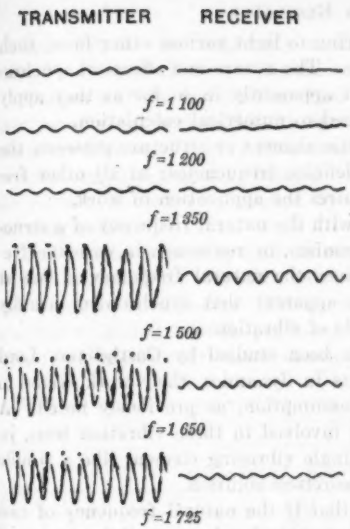

FIG. 3(a).—VIBROGRAPH OF CORKBOARD, 6 BY 6 BY 6 IN.

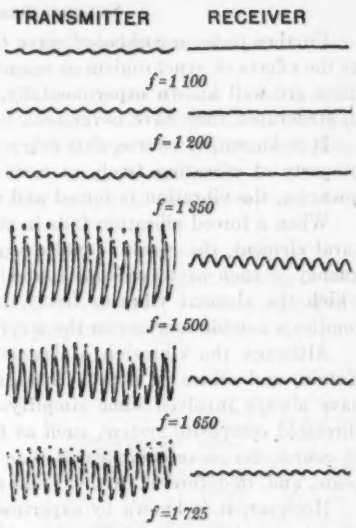

FIG. 3(b).—VIBROGRAPH OF CORKBOARD, 6 BY 6 BY 12 IN.

decreases greatly and suddenly, while that of the receiver is not materially affected. This does not mean that the damping effect is lost, but that this particular frequency corresponds to a critical point, or node, of the transmitter. This further indicates the value of carrying such vibration experiments over a considerable range of loads and frequencies, because the results obtained at a critical point have a special rather than a general significance.

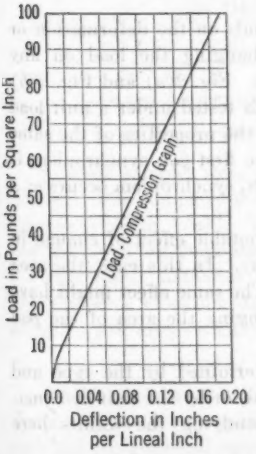

FIG. 4.—COMPRESSIBILITY OF CORKBOARD.

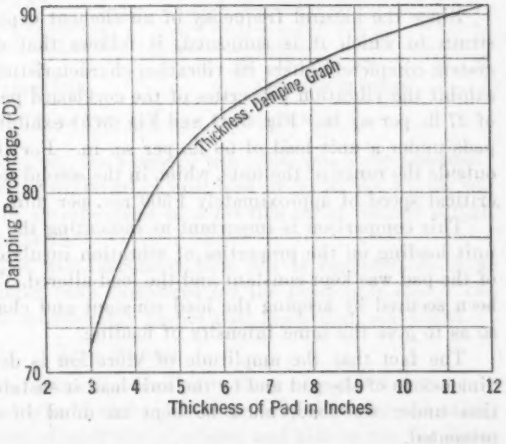

FIG. 5.—EFFECT OF THICKNESS ON DAMPING.

## Synchronism or Resonance

Further tests on corkboard serve to bring to light various other facts, such as the effects of synchronism or resonance. The nature and effects of synchronism are well known experimentally, but apparently in so far as they apply to structures, they have never been reduced to numerical calculation.

It is known, of course, that every elastic element or structure possesses the property of vibrating freely at certain definite frequencies; at all other frequencies, the vibration is forced and requires the application of work.

When a forced vibration falls in step with the natural frequency of a structural element, the result is called synchronism, or resonance in case the frequency is such as to produce sound. Since the natural frequency is one at which the element vibrates freely, it is apparent that synchronism usually implies a notable increase in the amplitude of vibration.

Although the vibration of beams has been studied by Castigliano, Lord Kelvin, and others of notable attainments in dynamics, their work seems to have always involved some simplifying assumption, as previously noted. A threefold composite system, such as that involved in these vibration tests, is, of course, far more complicated than a single vibrating element like a simple beam, and, therefore, is further from a theoretical solution.

However, it is known by experiment that if the natural frequency of two elastic systems are denoted by $f_1$ and $f_2$, respectively, the natural frequency of the composite system, in general, will be neither $f_1$ nor $f_2$. An insulating pad, such as those tested, also has a marked effect on the natural frequency of the composite system. This effect of insulation was studied by Berger,[3] who found that the nature of the material, as well as the area and thickness of the pad, affected the amplitude of vibration and the natural frequency, or point of synchronism. He found, for example, that at a given frequency, an insulating pad of improper dimensions might serve to intensify the amplitude of vibration.

Since the natural frequency of an element depends on the deformation or strain to which it is subjected, it follows that changing the load on any system completely alters its vibration characteristics. Fig. 2(*a*) and Fig. 2(*b*) exhibit the vibration properties of the corkboard pads tested under a unit load of 27 lb. per sq. in. Fig. 3(*a*) and Fig. 3(*b*) exhibit the properties of the same pads under a unit load of 50 lb. per sq. in. For the first set, synchronism is outside the range of the tests, while, in the second test, synchronism occurs at a critical speed of approximately 1 500 rev. per min.

This comparison is important as indicating the notable effect of change in unit loading on the properties of vibration insulators. In this case, the area of the pad was kept constant and the load altered. The same effect might have been secured by keeping the load constant and changing the area of the pad so as to give the same intensity of loading.

The fact that the amplitude of vibration is determined by the type and dimensions of the pad and by the unit load it sustains, or by the unit deformation under the load, must be kept in mind in studying the results here presented.

[3] *Gesundheits Ingenieur*, 1913, Vol. 36, p. 433.

### Hair Felt Insulation

Hair felt is very commonly used for sound absorption, and, to a more limited extent, as vibration insulation for machinery.

The basis of the felt used in these tests is said by the makers to be animal hair, compressed and milled by special processes, and sealed by a proofing solution which enables it to withstand high unit compression; it also increases its resiliency, and makes it damp-proof. When used as machinery insulation, the surface is further protected by applying a special oil, water, and fire-resisting paint.

The samples were 3 by 2 in. in area, and in four thicknesses, namely 1 in., ½ in., ¼ in., and ⅛ in. The first two samples were used together, making a test pad, 3 by 2 by 1½ in. in size. The average density was 0.397, which is equivalent to a unit weight of 2.066 lb. per board-ft. Its properties under load are apparent from the load-deflection curve shown in Fig. 6(*a*).

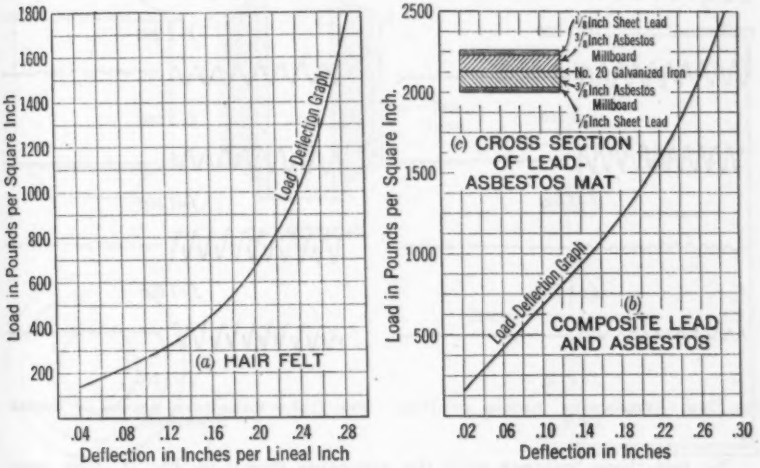

Fig. 6.—Properties of Two Types of Vibration Mats.

As these samples were so small, the range of test loads was correspondingly limited. For comparison with corkboard, a unit load of 50 lb. per sq. in. was applied (see Fig. 7(*a*)). The average value of $k$ for this set of records is 0.21, and the damping percentage is 79.

This result indicates that well-fabricated hair felt is considerably more effective as a vibration damper than corkboard for the same unit load. The material will also withstand considerably higher unit loads than corkboard.

### Live Rubber

This material has resilient properties similar to those of corkboard and felt. Tests were made on a special type of rubber bushing used for engine mounting, both for the practical interest of such use of rubber, and also to test the claim that it possesses better damping properties in shear than in compression.

As shown in Fig. 8(*b*), these mountings comprised inner and outer metal sleeves, united by a moulded rubber bushing, through which the load was transmitted in shear from one steel sleeve to the other. These bushings are intended to be mounted axially, putting the rubber in shear and loading it symmetrically and uniformly. Evidently, they would be much less effective as vibration dampers if mounted radially, since only a small part of the rubber would be in action, and even on this segment the load would not be distributed uniformly.

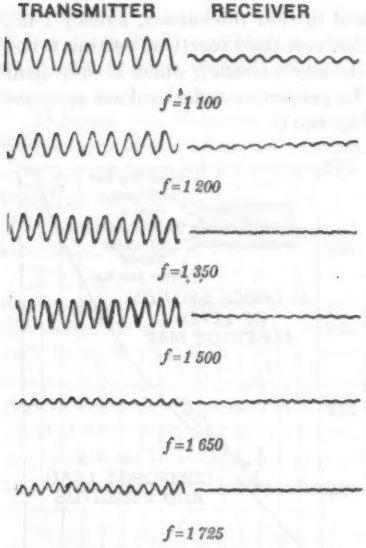

FIG. 7(*a*).—VIBROGRAPH RECORD OF HAIR FELT.

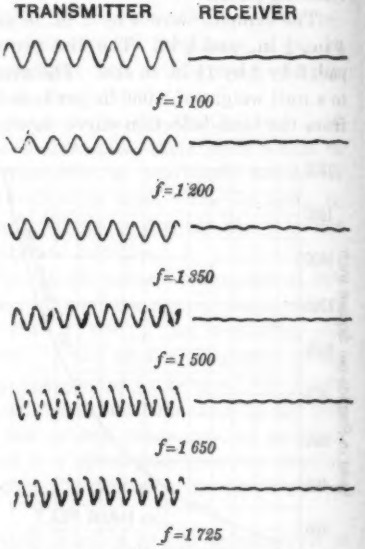

FIG. 7(*b*).—VIBROGRAPH RECORD OF RUBBER BUSHINGS.

To test these bushings with the apparatus shown in Fig. 1, they were mounted in pairs in a short section of pipe, as shown in Fig. 8(*c*). Two such pairs, or four bushings, were then used as legs for supporting the end of the H-beam on the test platform. With this arrangement, each pair carried one-half the reaction at the end of the H-beam, and this load passed through two bushings. Each one thus carried exactly the same load, but as the vibration passed through two bushings in series, the amplitude of vibration was damped twice as much as for a single bushing.

The manufacturer's rated loading for this type of bushing is 150 to 200 lb. per bushing. They were tested as vibration dampers in the manner just explained under three different loads, the vibrograph records in Fig. 7(*b*) being for a load of 224 lb. per bushing.

The average damping factor determined from this test was 0.096 per pair in series. For a single bushing, therefore, the value would be approximately

twice this amount, or $k = 0.19$. Consequently, the percentage of damping for bushings of this particular type and loading is found to be 81. For a load of 160 lb. per bushing, the damping percentage was found to be 85.

### Asphalt Emulsion

One of the most important forms of vibration insulation in structural work is lateral insulation around piers and column footings. For this purpose a light grade of corkboard is often used because the insulation is introduced simply as a separator and transmits no load. Plastic or semi-fluid materials might also be used as lateral insulation, simply poured into cracks. With this in mind, an asphalt emulsion was tested to determine its properties as a vibration damper. This was received in a semi-fluid condition.

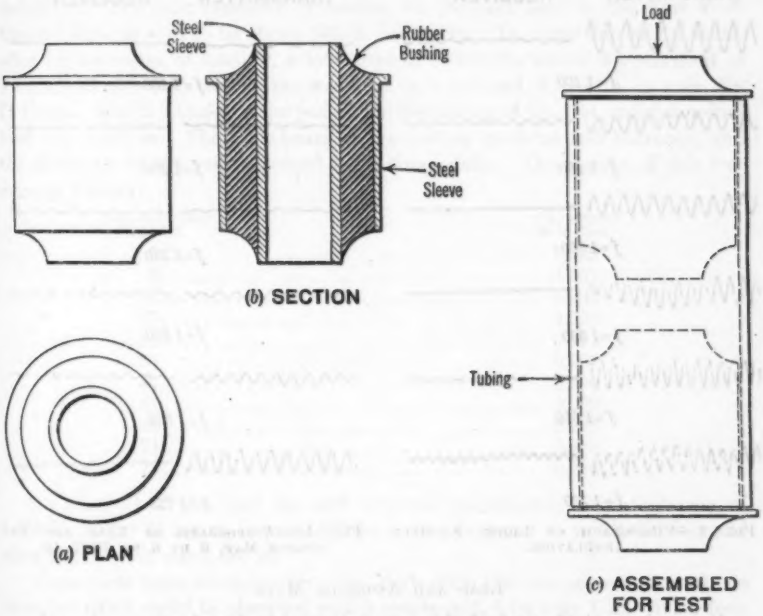

Fig. 8.—Rubber Bushing Used for Vibration Tests.

To test the material in this state, it was necessary to confine it in a rectangular tin can, 9 by 6½ by 4 in. This container was filled with the asphalt emulsion until it bulged and was then placed on the test platform with its 4-in. dimension vertical. A square steel plate, 6 by 6 by 1½ in., was placed on the can, and this, in turn, supported the end of the H-beam, or receiver. In shape and dimensions, this test pad was, therefore, very similar to the corkboard pads tested. In the case of lateral insulation, the load is nominal. A light load of 396 lb. (11 lb. per sq. in.) was applied therefore to the steel plate. The vibrograph records for this test are shown in Fig. 9. These give an average value of $k = 0.113$, or a damping percentage of 88.7.

This material dries out in air, however, and although it does not completely harden, but remains plastic or sticky, it possesses little or no resilience. Therefore, although it would not transmit vibration like a rigid body under any conditions, its effectiveness as a vibration damper would be relatively small.

However, this test was otherwise useful as confirming the results obtained with resilient materials, such as corkboard, felt, and rubber, since the can with its semi-fluid contents was highly resilient, offering very slight resistance to deformation and resuming its shape instantly on removal of load. The results of this test, therefore, confirm fully the general conclusion that the qualities essential to an effective vibration insulator are slight resistance to deformation and complete resilience.

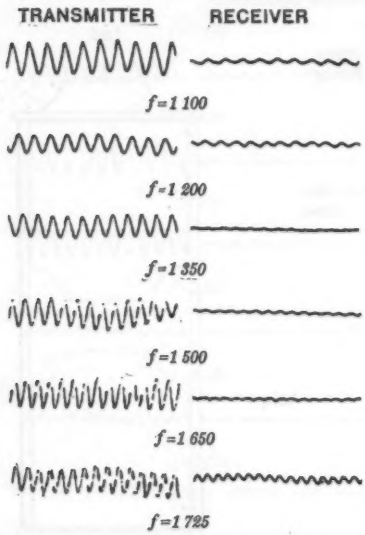

FIG. 9.—VIBROGRAPH OF LIQUID ASPHALT INSULATION.

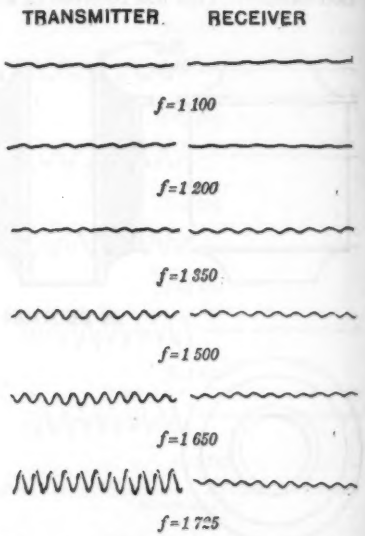

FIG. 10.—VIBROGRAPH OF LEAD AND ASBESTOS MAT, 6 BY 6 BY 10.75 IN.

## LEAD AND ASBESTOS MATS

Composite pads formed of alternate layers of lead and asbestos have been used extensively by the New York Central Railroad Company in the Terminal Zone, New York, N. Y., as vibration mats under column footings. A large number of tests, therefore, were made on such pads to determine their properties as vibration dampers, as well as their physical properties with respect to resilience and deflection or lateral deformation under load. The pads tested were identical in make-up with the vibration mats used in the construction of the Graybar Building,[4] New York, which were originally devised as sound deadeners. They have proved effective in eliminating low pitched noises of approximately 50 oscillations per sec.

[4] *Engineering News-Record*, February 10, 1927, pp. 228–230.

The standardized mat adopted in this work consists of five separate layers, as shown in Fig. 6(*c*). The bottom layer of sheet lead is turned up and folded over the top layer as a protection against water. Care was taken, in making up the test pads, to use the same quality of asbestos millboard, from the same manufacturers, as specified for the vibration mats used in the Graybar Building. The total thickness of such a composite pad is approximately 1⅛ in.

To determine this deformation under heavy loads, a sample pad, 6 by 6 in. in area, was tested in compression up to a total load of 100 000 lb., which is equivalent to a unit load of 2 778 lb. per sq. in. The load-deflection curve obtained from this test is shown in Fig. 6(*b*). No lateral spreading of either lead or asbestos layers could be detected at any load.

A second test was made on a similar pad to observe the effect of time on deflection. The unit intensity of loading on the pads used in the New York Central Zone is said to be about 500 lb. per sq. in. To cover this and a somewhat higher range of loading, a total load of 30 000 lb., which is equivalent to a unit load of 833 lb. per sq. in., was kept on a test pad, 6 by 6 in. in area, for 75 hours. The thickness of the pad at the beginning of the test under nominal load was 1.088 in. The scale-beam of the testing machine was balanced, and the thickness of the pad measured three times daily. The results of this test were as follows:

| Elapsed time, in hours. | Thickness, in inches. |
|---|---|
| 0 | 1.022 |
| 3 | 0.997 |
| 7 | 0.994 |
| 23 | 0.993 |
| 27 | 0.991 |
| 31 | 0.991 |
| 47 | 0.990 |
| 51 | 0.989 |
| 55 | 0.989 |
| 71 | 0.988 |
| 75 | 0.988 |

On removal of the load the pad returned immediately to a thickness of 1.039 in.; after 24 hours, it was 1.060 in.; after 48 hours, it was 1.076 in.; and after 96 hours, it was 1.086 in.

These pads were so extremely solid that, with the test apparatus used, no damping effect could be observed with a single pad, 6 by 6 by 1 in. With four such pads piled together, making a test block, 6 by 6 by 4⅛ in., the damping effect was still so slight that its numerical value could not be definitely determined.

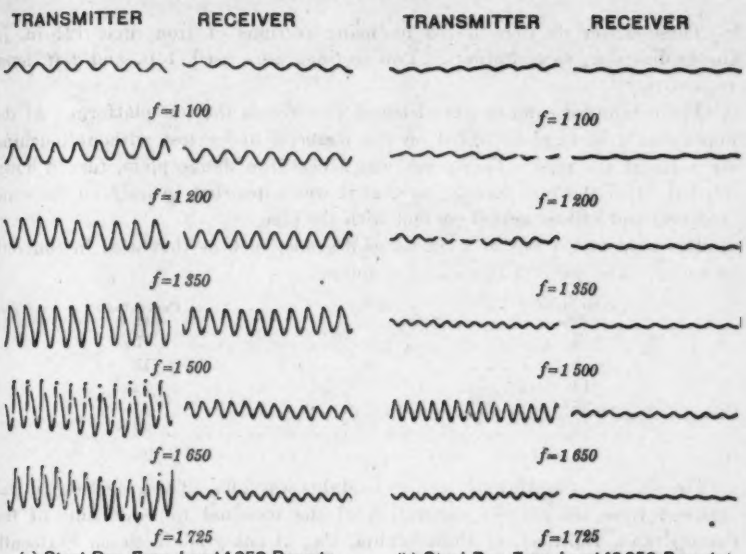
To amplify the damping effect sufficiently to get more pronounced and reliable results, ten such pads were piled together. In two of these pads the thickness of the asbestos layers was ½ in. instead of ⅜ in.; in all other respects, the pads were exactly identical. This composite tenfold test pad, comprising altogether 40 layers of sheet lead, 40 layers of asbestos millboard, and 20 sheets of galvanized iron, made up a block, 6 by 6 in. in area by 10¾ in. deep. It was tested for the full series of loads, ranging from 1 500 to 24 000 lb. on the scale-beam of the testing machine, which was equivalent to unit loads on the pads ranging from 35 to 450 lb. per sq. in.

Typical results from this series of tests are shown in Fig. 10. For a unit load of 450 lb. per sq. in., the average value of the damping ratio is $k = 0.48$, and, consequently, the percentage of damping for ten pads is 52. When the unit load was 340 lb. per sq. in., $k$ was 0.45 and $D$ was 55%; and with a unit load of 62 lb. per sq. in., the results were the same.

The average for the entire test series, comprising 228 vibrograph readings, and unit loads ranging from 35 to 450 lb. per sq. in., $k$, was found equal to 0.51, and, consequently, the total average damping percentage for ten pads was 49. The results indicate that as the unit load on the pad increases, the damping effect diminishes, which is confirmed by the results obtained with other materials comprised in this series of tests.

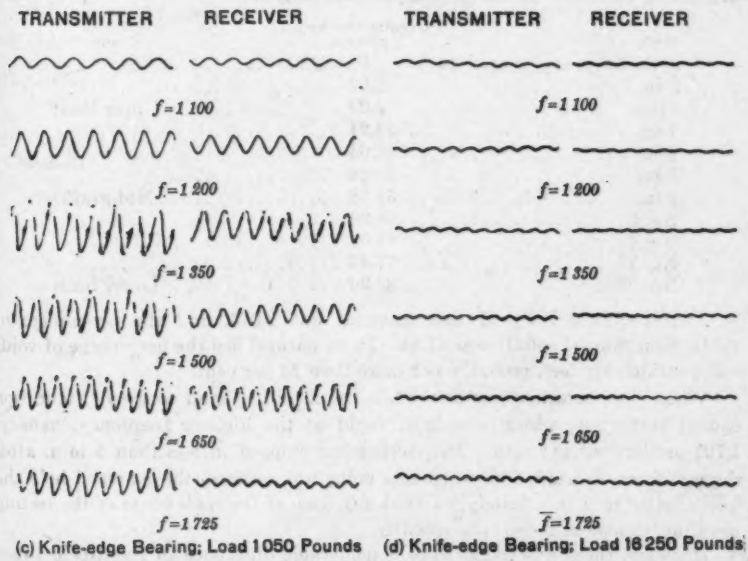
For a single pad of this type, of nominal thickness of 1 in., carrying a unit working load of 450 to 500 lb. per sq. in., and for the low frequencies covered by the tests (1 100 to 1 725 oscillations per min.), the percentage of amplitude of vibration damped out may be fixed at about 5.

### Effect of Constraint



A series of vibrograph records was taken with the test pad replaced by a machined steel bar, 15 by 3¼ by 1½ in. in size, placed on edge and crosswise, on the test platform; that is, with the 3¼-in. dimension vertical. The steel plate forming the test platform was also machined, and these were solidly clamped together. As might be anticipated, the vibrograph records taken under these conditions showed no damping effect.

When the clamps were removed, however, so that the bar was free from the plate, except for the load holding them together, the vibrograph records showed a notable damping effect. In Fig. 11($a$) and Fig. 11($b$), the load is 156 and 203 lb. per lin. in. of contact, respectively. This indicates that a non-rigid connection between two structural members transmitting load, equivalent to lack of constraint, has a pronounced effect in damping the transmission of vibration between these members. To verify this further, the machined steel bar was replaced by a knife-edge bearing, 4 in. long. The results for a light and a heavy load are shown in Fig. 11($c$) and Fig. 11($d$).



For the light load, the results shown in Fig. 11($a$) and Fig. 11($c$) are very similar. For the load of 16 250 lb., it is to be noted that the width of the H-beam, or receiver, was 8 in., and, therefore, the load per linear inch in Fig. 11($b$) was 2 031 lb., whereas the knife-edge bearing was only 4 in. long, and, consequently, the load in Fig. 11($d$) was 4 062 lb. per lin. in. of contact.

In Fig. 11($d$) the amplitudes are very much less than in Fig. 11($c$), due to the greater load and, consequently, smaller relative effect of the forced vibration. However, the ratios of amplitudes in both diagrams are almost exactly the same, giving an average damping percentage in both cases of 45. The actual numerical value of this damping factor, however, is not of special importance; the chief feature is that damping of a substantial amount results from lack of constraint.

This general principle, that lack of constraint damps the transmission of vibration, may be applied to great advantage in structural design in numerous ways. It also serves to explain the properties of sand and gravel as vibration dampers.

(a) Steel Bar, Free; Load 1250 Pounds (b) Steel Bar, Free; Load 16 250 Pounds

(c) Knife-edge Bearing; Load 1050 Pounds (d) Knife-edge Bearing; Load 16 250 Pounds

FIG. 11.—VIBROGRAPHS WITH SOLID STEEL PLATE AS INSULATION MEDIUM.

### Sand and Gravel

These materials were tested by using sections of iron pipe, 12¼ in. in inside diameter, as containers. Two sections were used, 1 ft. and 2 ft. long, respectively.

The column of sand or gravel rested directly on the test platform. At the upper end a cover-plate rested on the material under test without touching the sides of the pipe. This cover was a cast-iron flange plate, turned down until it fitted the pipe loosely, so that it was supported entirely on the sand or gravel and had no actual contact with the pipe.

The sand tested was of a commercial grade, such as that used in concrete mixtures. The sieve analysis was as follows:

| Tyler sieve, No. | Percentage coarser. |
|---|---|
| 4 | 5 |
| 8 | 13 |
| 14 | 22 |
| 28 | 43 |
| 48 | 83 |
| 100 | 95 |

The value of the Abrams fineness modulus was 2.65. The gravel tested was obtained from the subway excavation of the terminal improvements of the Pennsylvania Railroad, at Philadelphia, Pa., at sub-grade between Sixteenth and Seventeenth Streets. It was found to be glacial drift, ground up to all degrees of fineness. The sieve analysis was as follows:

| Mesh. | Percentage by weight, coarser. | Limits. |
|---|---|---|
| 2½-in. | 0 | ..... |
| 2-in. | 2.02 | ..... |
| 1½-in. | 9.09 | Upper limit |
| 1-in. | 24.24 | ..... |
| ¾-in. | 30.64 | ..... |
| ½-in. | 41.08 | ..... |
| ⅜-in. | 51.18 | Mid-grain |
| No. 3 | 56.90 | ..... |
| No. 6 | 68.69 | ..... |
| No. 10 | 77.44 | ..... |
| No. 20 | 89.90 | Lower limit |

The specific gravity of this material was 2.373, and the percentage of voids when tamped solidly was 21.54. In its natural bed the percentage of voids was considerably less, probably not more than 12 per cent.

When the container was newly filled with either sand or gravel, vibration caused settlement which was most rapid at the highest frequency, namely, 1 725 oscillations per min. This settlement stopped in less than 5 min. after the motor was started, and, when this point was reached, the material held the load applied to it indefinitely, without any drop of the scale-beam of the testing machine, except as noted subsequently.

However, there was found to be considerable difference in stability between the sand and the gravel. When the container was filled with sand, and a cover-

plate 12 in. in diameter was used, leaving a clearance of $\frac{1}{8}$ in. all around between cover and pipe-wall, there was no settlement at the lower frequencies, but, at 1 725 oscillations per min., the sand began to rise through the crack and the cover-plate settled accordingly.

This did not happen with gravel. To test its stability under vibration, a cover-plate only 10 in. in diameter was tried, thus leaving a clearance of $1\frac{1}{2}$ in. all around, between cover and pipe-walls. Although none of the material near the top of the container was larger than $\frac{1}{2}$ to $\frac{3}{4}$ in. in diameter, it showed no tendency to rise through this wide opening or crack, and it was found possible to maintain a constant load at any frequency within the speed limits of the motor. Since the vibrograph records taken did not show any difference between sand and gravel as regards their properties as vibration dampers, the conclusion is that it is advantageous to use gravel rather than sand as subfoundation material because of its greater stability and because it is less liable to shift and settle under vibration.

As regards vibration properties, sand and gravel are essentially different from materials like cork, rubber, felt, and asbestos. The latter are all compressible and resilient, whereas sand and gravel are incompressible and nonresilient. Referring to the vibrograph records for cork, felt, and rubber (Figs. 3 and 7), it is evident that their action as vibration dampers, or, more properly, as insulators, is due to the fact that they act like a spring, permitting a certain dynamic freedom, or independence, between the two systems, without affecting the static load transmitted. Lacking such resilient properties, there is of course still the possibility that sand and gravel may absorb energy of vibration by internal work or frictional resistance between the particles. This possibility, therefore, must be examined.

It seems obvious that if there was sufficient motion between the particles of sand or gravel to absorb the energy of vibration by internal work, they would not show the stability they are known to possess. On this feature considerable information may be gained from seismology. On seismograph records, such as those taken at the U. S. Bureau of Standards, two sets of waves are clearly distinguishable. In fact, they form a characteristic feature of such records. When an earthquake is recorded on this instrument, there first appears a compression wave of relatively small amplitude, which is supposed to travel in practically a direct line from the disturbance through the earth's crust, that is, within a layer possibly 1 000 miles in depth. After a considerable interval of time a second wave suddenly makes its appearance, of much greater amplitude than the first. This is said to be a surface wave traveling close to the surface of the earth.

The amplitude of these waves is the important feature from the standpoint of the action of such materials as rock, soil, gravel, sand, etc., as vibration dampers. This may be illustrated from actual records taken on the seismograph at the U. S. Bureau of Standards, which has an amplification ratio of 1 000.

For example, the surface wave from an earthquake 2 000 miles distant, traced a graph 4 in. in width. The surface wave from an earthquake under

the Pacific Ocean, 10 000 miles distant, traced a graph fully 1 in. in width. An earthquake in Bulgaria, 7 000 miles distant, traced a graph for the surface wave more than ¾ in. in width.

It would seem to be possible from a comparison of such records to study the damping effect of distance traveled on the amplitude of vibration, but apparently very little has been done along this line. Experimental data obtained during the World War on location of guns by means of soil vibration, indicated that vibration set up by gun-fire was observable for a distance of ¾ mile. In prospecting for oil, soundings are made by noting the time required for vibrations set up by the explosion of a depth charge to reach the surface, but practically no data are available as to the effect of distance traversed on damping the amplitude of vibration. It is sufficiently evident, however, from these and similar instances that within the limited distance of a few feet there can be no marked damping effect due to absorption of the energy of vibration by internal work. Whatever damping properties sand and gravel may possess, therefore, must be independent of the depth of the material within the actual limits usually met in engineering practice.

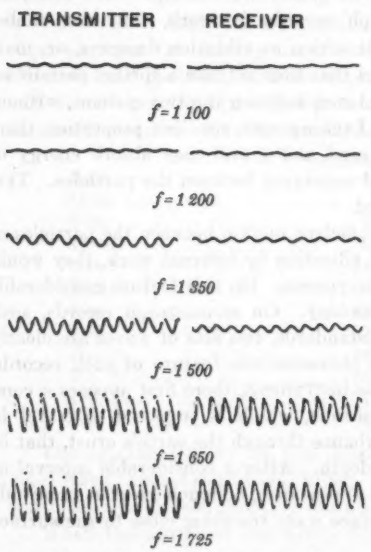


FIG. 12(a).—VIBROGRAPH OF 12-INCH LAYER OF SAND, LOADED TO 19 LB. PER SQ. IN.

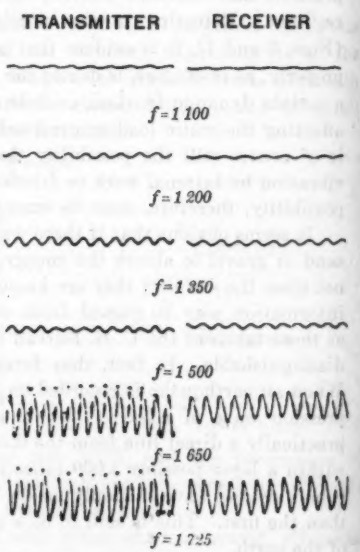

FIG. 12(b).—VIBROGRAPH OF 24-INCH LAYER OF SAND, LOADED TO 19 LB. PER SQ. IN.

In the course of this investigation, however, a large number of vibrograph records were taken with both sand and gravel. Typical results from these tests are shown in Figs. 12 and 13. The general conclusion is that such damping of vibration as results from the use of sand or gravel is a surface effect, similar to that which results from any looseness or lack of rigidity in a struc-

tural connection through which the forced vibration is transmitted. A practical instance of this effect may be noted along any railroad track in the motion of the ties on the ballast when a train passes. Such freedom damps the vibration at the source, localizing the disturbance instead of transmitting it elsewhere, as would be the case if the track were rigidly supported on a steel viaduct or solid masonry.

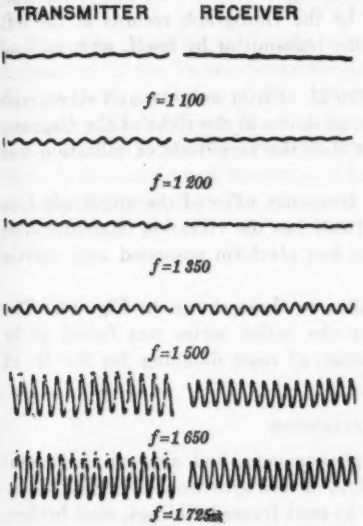

FIG 13.—VIBROGRAPHS OF GRAVEL SAMPLE, 24 IN. DEEP, LOAD, 19 LB. PER SQ. IN.

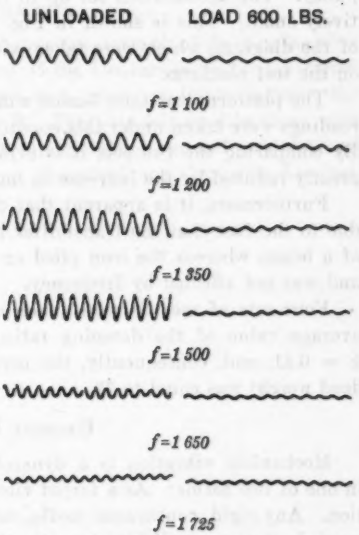

FIG. 14.—VIBROGRAPHS SHOWING EFFECT OF MASS DAMPING.

## MASS DAMPING

Mass may be used as an inertia damper to reduce the amplitude of a forced vibration. For example, in the case of a large Diesel engine, the bed-plate is usually so heavy that no vibration whatever can be felt while standing on it; yet at some point in a structure remote or near-by, there is often a serious vibration. Evidently, this was transmitted from the engine through the bed-plate, but the acceleration it produced in the relatively large mass was so small as to be imperceptible. It re-appears, however, as a large acceleration in some structural member of relatively small mass, the natural frequency of which happens to synchronize with the engine speed.

It may be noted, however, that when a massive foundation is used under machinery, although apparently it may be effective as a vibration damper, it is not a proper substitute for dynamic balancing because it is inefficient from the standpoint of power losses and strain on the frame of the machine.

With the apparatus used in these tests, the forced vibration was produced by a relatively small mass, namely, the unbalance of the pulley moving at a

high acceleration. The radius of this "unbalance" was $1\frac{3}{4}$ in.; therefore, at the highest speed of 1 725 rev. per min. the centripetal acceleration was:

$$\frac{1.75}{12}\left(\frac{2\pi\,1\,725}{60}\right)^2 = 4\,759 \text{ ft. per sec.}$$

The steel I-beams, motor, and test platform of which the test apparatus was made up, were relatively very heavy with respect to the "unbalance" on the pulley. The acceleration set up in these heavy members was, therefore, relatively small. This is shown in Fig. 14 by the vibrograph records at the left of the diagram, which were taken with the transmitter by itself, with no load on the test platform.

The platform was then loaded with 600 lb. of iron weights, and vibrograph readings were taken under this condition, as shown at the right of the diagram. By comparing the two sets it is evident that the amplitude of vibration was greatly reduced by the increase in mass.

Furthermore, it is apparent that the frequency affected the amplitude less, due to the fact that the transmitter by itself has the vibration characteristics of a beam, whereas the iron piled on the test platform possessed only inertia and was not affected by frequency.

Four sets of records were taken similar to those shown in Fig. 14. The average value of the damping ratio for the entire series was found to be $k = 0.21$, and, consequently, the percentage of mass damping for 600 lb. of dead weight was equal to 79.

## General Conclusions

Mechanical vibration is a dynamic phenomenon, and appears in general in one of two forms: As a forced vibration, or as a synchronous or free vibration. Any rigid, continuous media, such as steel frame buildings, steel bridges or viaducts, or monolithic concrete structures, serve as excellent conductors of vibration, but no data are available as yet with respect to the relative conductivity of different types of construction as regards vibration.

To prevent the transmission of vibration, it should be "short-circuited" or confined to a limited region as close as possible to the source from which it originates.

For relatively light loads, such as machinery, there are many different media which may be used for isolation purposes. These depend on resilience for their insulating properties. None of them dissipates the energy of vibration by internal work or molecular friction to any appreciable extent.

For heavy loads, such as occur on piers and footings of tall buildings, the materials available for insulation are limited, and their resilience and damping properties are restricted to relatively narrow limits.

Synchronous vibration may be prevented entirely or eliminated by such modification in the design of the part affected as shall throw its natural frequency out of step with the exciting frequency.

Sand and gravel when used as insulators do not absorb the energy of vibration by internal friction; they owe such effectiveness as they possess to their lack of rigidity. Their insulating property is, therefore, largely a surface effect.

Vibrations of high frequency and relatively small amplitude are the most objectionable from a physiological standpoint.

These tests and such other data as are available, indicate that valuable results may be anticipated from research on the effect of modifying structural detail with a view to damping vibration without recourse to resilient insulators, especially as relates to vibration arising from subway operation and street traffic.

## Acknowledgments

The tests on which this study is based, were performed in the Engineering Laboratory of the Towne Scientific School of the University of Pennsylvania. The research facilities of this laboratory were made available through the courtesy of H. C. Berry, M. Am. Soc. C. E. The hair felt used in these tests was a product especially prepared for machinery insulation and was obtained through the courtesy of Mitchells, Ashworth, Stanfield, and Company, Limited, of London, England.

## DISCUSSION

J. P. DEN HARTOG,[5] ESQ. (by letter).—The paper deals with a subject of great interest, on which little research has been done. The general problem of vibrations in structures as well as in machinery is quite complicated, as Mr. Slocum remarks, and it is too often discussed in a purely empirical manner. It is possible, however, to give a perfectly rational explanation of many of these phenomena, including that which is the subject of this paper.

The author states that "no practical solution has yet been found of the vibration characteristics of such a primary element as a simple beam of uniform cross-section under load." This is not entirely true, since Rayleigh's method[6] gives, with very little calculation, a solution which is at least 95% correct; it is a "practical solution." If one wants to put some more work into the problem, Ritz's method[6] can be used, giving a solution in a series form to any desired accuracy. Both these methods are extensively used by vibration engineers.

The experimental set-up of Fig. 1 can also be completely calculated if the full data concerning the masses, flexibilities, and damping constants of the various members are known.

These items are not given in the paper. The elements that are least known in this set-up are the "load from the testing machine" and the flexibility of the supports between the I-beams and the platform.

The "load from the testing machine" consists partly of mass or dead weight and partly of spring pressure. These two causes have the same effect in compressing the test pad; but they behave radically different, dynamically. From the results in Fig. 2 (*a*), however, certain tentative conclusions can be drawn.

In the first place, the curve in Fig. 4 with the data in the description of Fig. 2 (*a*) makes it possible to calculate the spring constant of the test pad, which is 3 000 lb. per in. of deflection. This is so flexible as compared with the H-beam, that the latter flexibility can be safely neglected. The system of the test pad, H-beam, and testing-machine head then can be represented by Fig. 15.

Let $k_1$ (= 3 000 lb. per in.) represent the spring of the test pad, while $M$ and $k_2$ are the equivalent mass and spring caused by the H-beam and the testing-machine head. If this system is subjected to a vibratory motion, $a \sin \omega t$, at its bottom end, the mass, $M$, has a motion, $b \sin \omega t$, in which,

$$b = a \times \frac{k_1}{k_1 + k_2} \frac{\omega_n^2}{\omega_n^2 - \omega^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Equation (3) is the principal formula of the spring vibration absorber. In this formula, $\omega_n^2 = \dfrac{(k_1 + k_2)}{M}$, is the natural frequency of the system.[7]

[5] Research Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

[6] A description of Rayleigh's as well as of Ritz's method can be found in "Vibration Problems in Engineering," by S. Timoshenko, D. Van Nostrand Co.

[7] The complete theory can be found in the *Electric Journal*, Vol. XXI (1924), p. 160, in an article by C. R. Soderberg and, also, in the book by Timoshenko previously noted, p. 33.

The ratio, $\frac{b}{a}$, of the amplitudes of the "receiver" and the "transmitter", as calculated from Equation (3), has been plotted in Fig. 16. The curve shows that for very slow motions ($\omega = 0$) the ratio, $\frac{b}{a}$, is equal to $\frac{k_1}{(k_1 + k_2)}$; that is, the "static" condition. At a certain speed, ($\omega = \omega_n$), resonance occurs and the motion becomes infinite theoretically. For very fast motions of the bottom end ($\omega = \infty$), the mass, $M$, is too inert to follow it, and its amplitude is zero.

It is seen that the vibration absorber works only when its impressed frequency is high with respect to its natural frequency, which is another way of stating that a soft spring is needed. It is seen that for a stiff spring the absorber may become injurious; that is, the received vibration may be larger than the transmitted vibration. The test results indicate that they were conducted at the extreme right of the diagram of Fig. 16. In fact, it is possible that in the present test set-up there is some low running speed in which the amplitudes received are larger than those transmitted.

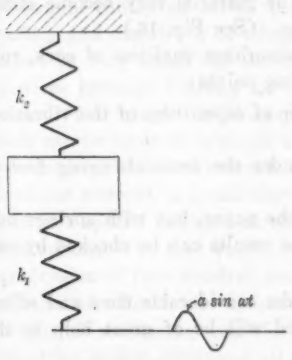

FIG. 15.—SCHEMATIC ARRANGEMENT OF TEST PAD, H-BEAM, AND TESTING MACHINE HEAD.

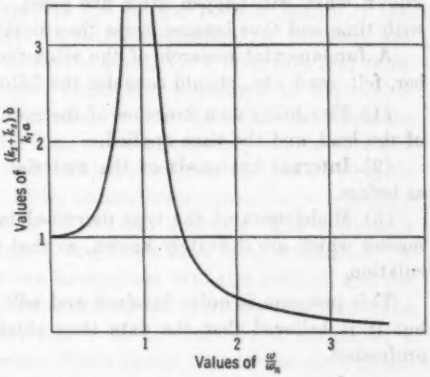

FIG. 16.—CURVE SHOWING THE RATIO, $\frac{b}{a}$, OF THE AMPLITUDE OF THE RECEIVER TO THAT OF THE TRANSMITTER AS A FUNCTION OF THE FREQUENCY OF THE INPUT VIBRATION.

In case the unbalanced motor had been placed on the H-beam directly above the test pad, while replacing the equivalent dead weight of the motor in its original location on the I-beams, the vibration of the I-beams would still be larger than that of the H-beam (at speeds from 1 100 to 1 500 rev. per min.). In this case, again, the result would be a "negative damping".

If, instead of corkboard, steel springs of the same flexibility had been used, the results would have been very much the same, since the tests were taken for points that do not coincide with the critical speed of the system in Fig. 15, so that internal friction of the material is of no importance.

The resonant frequency of the I-beams cannot be appreciably affected by the remainder of the system since the flexibility of the test pad is so great. A

rough calculation of this frequency from the available data indicates a higher frequency than the records show. A possible explanation for this is that the supports between the I-beams and the test platform have some flexibility, or that the test platform itself is not entirely steady.

When the corkboard test sample is replaced by sand or gravel, which have a higher modulus of elasticity, the $k_1$ of Equation (3) becomes larger and, consequently, the condition is displaced toward the left in Fig. 16, thereby showing a larger transmitted vibration.

Summarizing, it can be stated that proper vibration absorption can be accomplished fundamentally by supporting the vibrating system on such springs that the natural frequency of the system becomes low with respect to the frequency of vibrations. This can be done by steel springs or by organic materials like cork, rubber, etc.

The writer has had some experience with these absorbers as applied to machinery, and generally has used steel springs, for the reason that present knowledge concerning organic materials is insufficient. It is quite possible to mount a structure on corkboard and get good immediate results, but it is not known what will happen after five years. The material may become stiffer with time and thus become worse than nothing. (See Fig. 16.)

A fundamental research of the vibration-absorbing qualities of cork, rubber, felt, sand, etc., should consider the following points:

(1) Flexibility as a function of the number of repetitions of the vibration, of the load, and the time applied.

(2) Internal hysteresis of the material under the same changing factors as before.

(3) Model tests of the type described in the paper, but with springs and masses which are definitely known, so that the results can be checked by calculation.

This program is quite involved and will take considerable time and effort, but it is believed that the data thus obtained will be of great help to the profession.

FRANCIS G. TATNALL,[8] ESQ. (by letter).—The subject of vibration is of importance as a new field of engineering and, by this time, should have its specialists and a quantity of experimental knowledge. This does not seem to be the case, however, because little definite information on vibration is available and few specialists seem to be in the field.

Vibration studies are a specialist's job, because even though frequency and amplitude of vibration can be fairly well catalogued for any structure, the more difficult question is encountered: "What is to be done about it?"

Damping and insulating are not the answers. These appear to be only makeshifts, usable until the time comes when vibration can be measured and predicted so that it can be cared for by proper design. The completed structure, or parts of it that can vibrate as a whole, must be designed so that their natural frequency will conveniently avoid any forced vibration that will tune in to set up resonance.

[8] Mgr., Test Equipment Div., Southwark Foundry & Machine Co., Philadelphia, Pa.

With existing apparatus the frequency and amplitude of vibration can be measured under actual working conditions. With this knowledge, the machine or structure under consideration can be re-designed, and then must be tested again to see whether its natural frequency is high enough or low enough to keep out of step with external forced vibration. There is too much "cut-and-try" in this method so that ninety-nine out of a hundred times it is still a laboratory procedure. In some few instances, this method is actually applied to commercial design.

The paper dealt with low frequency, large amplitude vibration. The method is a good laboratory test for comparing vibration dampers. Very much higher frequencies, taken from structures in the field under actual operating conditions, can be measured with existing apparatus. Furthermore, vibration can be recorded from a large number of points simultaneously. The double resistor type of electric telemeter has been frequently used for such purpose and to good effect.[9] This instrument is attached to the member to be investigated and vibration in the member changes the resistances of a pair of highly refined carbon resistors which proportionately unbalances a Wheatstone bridge. An oscillograph, connected across the apex of the bridge, records faithfully the frequency and amplitude of vibration. If twelve telemeters, for instance, are attached by very small cap screws to twelve points on a structure and their lead wires brought together at a panel board and connected to the twelve elements of a single oscillograph recorder, twelve simultaneous vibration records can be made on a single 12-in. film, and the frequency can be obtained by comparison with a thirteenth record. This record may be that of 60-cycle alternating current, a break-circuit Swiss chronometer operating a reflecting kicker, or a special tuning-fork marking off 0.01-sec. intervals. The equipment is first calibrated so that known values of amplitude have been established. A magnification of four hundred times can be obtained with this method, and the amplitude of vibration is measured from the actual wave on the film. The principle of measuring electrical unbalance on so sensitive a circuit as a Wheatstone bridge eliminates all inertia effects except that of the oscillograph vibrator which is infinitely small.

Frequencies up to 1 200 cycles per sec. can be recorded at the sensitivities requisite for this work, although frequencies as high as 8 000 cycles per sec. have been recorded. The frequency is limited by the natural period of the oscillograph vibrator. As sensitivity in recording increases, frequency decreases. In other words, the greater the magnification of amplitude, the less the frequencies that can be recorded. Most vibrations encountered in commercial engineering structures are less than 300 cycles per sec., so this permits high magnification. Errors in recording range from 3 to 10%, depending on the severity of vibration.

Perhaps the telemeter can furnish additional information on the subject of vibration. Perhaps it can extend the work of Mr. Slocum, so as to record the actual damping effect, in structures under service conditions, of the materials he has studied in the laboratory. It can surely pick out the resonance or

[9] See "Recent Developments and Applications of the Electric Telemeter," by O. S. Peters, *Technologic Paper No.* 247, U. S. Bureau of Standards.

synchronisms as illustrated in Fig. 17.[10] When resonance is attained, the oscillograph trace can be seen to rush to it as a peak and becomes fainter (see position marked 10th harmonic, 1 650 rev. per min., top line, Fig. 17). The heavy regular wave is the timing trace. The superimposed wave is the forced vibration in the part. When the natural frequency of the part is not

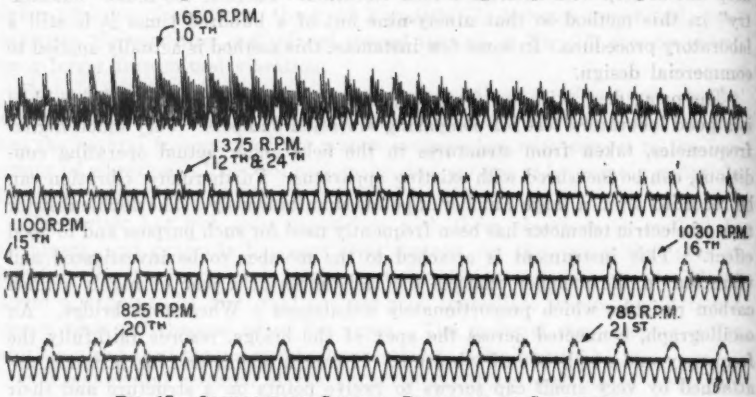

FIG. 17.—OSCILLOGRAPH SHOWING RESONANCE OR SYNCHRONISM.

approached this wave is regular and well defined, but when synchronism is reached, it flies all to pieces. The figures, 10th, 12th, 15th, etc., designate the harmonics, and the speeds noted are the rates of forced vibration.

By means of the telemeter, vibration can be measured, recorded, studied, and catalogued, but it must be remembered that there the function of the telemeter stops. What remedies to use to overcome the phenomenon is another problem entirely.

W. M. DAWLEY,[11] M. AM. SOC. C. E. (by letter).—A consideration of some of the fundamental equations of motion as derived by Mr. J. W. S. Rayleigh[12] leads one to question whether the arrangement of the test apparatus adopted by Mr. Slocum was the best for the purpose (see Fig. 1). The test pad at the center and the unbalanced rotor near the quarter-point of the transmitter I-beam with the plane of rotation at right angles to the length of the beams, would set up a harmonic overtone vibration in the beams having a period one octave above the normal period of the undamped beam, the latter period being more or less damped out. The test pad, therefore, rests at the nodal point in so far as the horizontal vibrations are concerned and does not respond fully to the impressed vibrations.

The test load applied to the one-third point of the H-beam acts as a damper to produce a node at that point. On the assumption that the flexibility of the test pad permits horizontal vibrations of that end of the H-beam resting on it, the period would be one octave above the normal period or "gravest node" of vibration of the beam with both ends fixed, but otherwise free.

[10] As recorded by the Cleveland Wire Spring Co.

[11] Engr., Land and Tax Dept., Erie R. R., Cleveland, Ohio.

[12] "Theory of Sound," by J. W. S. Rayleigh, Second Edition, 1894, reprinted 1926.

In discussing this phase of the problem, Messrs. J. Ormondroyd and J. P. Den Hartog, have shown that a simple steel bar, 2 in. by ¾ in. by 60 in., lying flat and simply supported at the ends and supporting a 26-lb. direct-current motor at its center with two 8-lb. weights, one attached at the quarter-point, and the other at the three-fourths point, of the length, had natural frequencies of 750 and 2 800 rev. per min.[13]

It would seem to have simplified the interpretation of results if the rotor, test pad, and load from the testing machine had all been placed in the same vertical plane. This plane would pass through the test pad at right angles to the beams, with the center of the rotor on a level with the steel plate under the test pad for horizontal motion tests, and vertically under the test pad for vertical motion tests.

The use of such an unbalanced rotor as that described by the author introduces undesirable variations which confuse the analysis. Up to a certain critical speed the motor armature, with its unbalanced pulley, will rotate about its geometric center and the force that produces vibration will be only that of the unbalanced component, a few ounces or pounds. At speeds greater than this critical speed the vibration will involve the whole mass of the armature and pulley as well. The tendency then is for the entire rotating part to revolve about the common center of gravity of armature and unbalanced weight, which is not the geometric center of the shaft. Since the unbalanced pulley is at one end of the motor shaft, that end of the motor will vibrate more than the opposite end at high speeds, thus tending to produce a rotary motion similar to that of a rotating pendulum, except that the axis of rotation is horizontal instead of vertical.

There is also the further complication that the phase of the vibration at speeds greater than the critical speed is almost, but not exactly, opposite the phase at speeds less than the critical and that the amplitude of vibration changes at the critical speed, being less at the higher speeds, as shown in Fig. 14. The effect of one or several unbalanced weights rotating in different parallel planes has been described at considerable length by Mr. R. Eksergian[14] in connection with the problem of dynamically balancing the reciprocating and rotating parts of a locomotive.

Viewed from another angle, consider the H-beam and the testing-machine load as a steady mass which it is desired to set in motion by means of the unbalanced weight on the motor pulley, and that the amplitude of the receiver graphs is a fair measure of the energy that has survived the trip through the transmitter I-beams and test pad.

There is not much variation in the energy transmitted under the conditions illustrated by Figs. 2, 7, 9, 10, 11(*b*), and 11(*d*). That is, approximately the same percentage of the energy developed by the unbalanced rotor is transmitted notwithstanding the fact that the more or less flexible test pads permitted the transmitter I-beams and plate to vibrate more or less freely. In other words, the amplitude of the vibrations set up in the transmitter beams is

[13] *Transactions*, Am. Soc. Mech. Engrs.; Applied Mechanics, Vol. 50, Paper 7; abstract in *Mechanical Engineering*, December, 1928, p. 975.

[14] *Transactions*, Am. Soc. Mech. Engrs., Vol. 51, No. 17; Railroads, Vol. 51, No. 5.

not the proper function to compare with the amplitude of receiver graphs to determine the efficiency percentage of the insulator pads.

The flexible I-beams interposed between the rotor and the steel plate on which the test pad rests should be eliminated, or the energy lost in setting the transmitter beams in vibratory motion should be ascertained by comparing the amplitude of the unloaded transmitter with that of the transmitter with the test pad and testing machine load applied.

However, transmitter graphs for $f = 1\,100$ shown in Fig. 7($a$) and Fig. 7($b$), seem to be inconsistent with this latter point of view, because the damped vibration of the lightly loaded transmitter shows a greater amplitude than the unloaded transmitter graph for the same speed shown in Fig. 14.

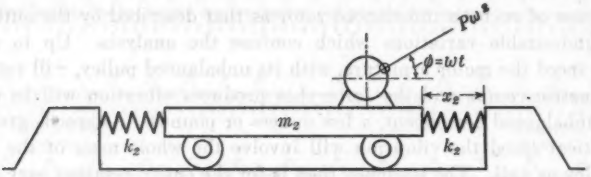

FIG. 18.

In the vibration research laboratory at Leland Stanford, Jr., University the shaking table[15] consists of a heavy platform mounted on four street-car wheels, and anchored by springs (in compression) to heavy concrete piers (see Fig. 18). The platform is made of 8-in. H-beams bolted and welded together; its dimensions are 10 by 12 ft. with a weight, $m_2$, of approximately 6 000 lb. In order to reduce the friction of the table motion to a minimum, the street-car wheels have been ground concentrically with their axles and mounted on ball bearings.

In considering the type of motion to be imparted to this table it was decided that it must be "a civilized" disturbance, a motion of the table that can be repeated again and again with great accuracy; and, if possible, it must be a motion that can be treated mathematically with some degree of comfort, in order that the accelerations and velocities involved may be known quite accurately.

These considerations have led to the adoption of two distinct types of linear motions, namely, a damped, free vibration of the table, resulting from an elastic impact of a pendulum; and a continuous, forced vibration, set up by a revolving unbalanced fly-wheel mounted on the shaking table. The two types of resultant motion are, of course, quite different. In the case of the pendulum, maximum acceleration occurs when the initial displacement is quite small and the succeeding maxima of the accelerations are each less than the preceding, the difference between the first and second being considerably greater than the difference between the succeeding maxima. The maxima of the accelerations are at maximum amplitudes. The damping of the free vibration is a combination of constant damping and velocity damping.

[15] See Lydik S. Jacobsen, in *Bulletin*, Seismological Soc. of America, Vol. 19, No. 1, March, 1929, Fig. 18.

In the case of the unbalanced pulley the resultant vibration of the table is very nearly a simple harmonic motion or sine curve.

The equation of motion is:

$$m_2 x_2'' + c_2 x_2' + k_2 x_2 = P \omega^2 \cos \omega t \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Integrated, this equation becomes:

$$x_2 = \frac{P \omega^2 \cos (\omega t - \psi)}{[c_2^2 \omega^2 + (k_2 - m_2 \omega^2)^2]^{\frac{1}{2}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which,

$\psi$ = arc tan $\dfrac{c_2 \omega}{k_2 - m_2 \omega^2}$;

$m_2$ = mass of table;

$k_2$ = characteristic of anchor springs;

$x_2$ = displacement of table;

$c_2$ = damping factor;

$P$ = the unbalanced moment;

$\omega$ = the angular velocity, in radians per second; and

$t$ = time, in seconds.

When resonance occurs, $\omega = \sqrt{\dfrac{k_2}{m_2}}$, and the displacement of the table is,

$$x_2 = \frac{-P \omega \sin \omega t}{c_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

The pulley is mounted on the table independently of the motor, and, judging from the photographic illustration, it appears to be 2 ft. or more in diameter. It is loaded with eight pigs of lead braced under the rim and a shot tank located between the spokes, which can be filled with any desired amount of shot and emptied without stopping the rotation, thus varying the amplitude at will by altering the amount of unbalance without changing the speed. The motor is also set on the table and is belt-connected with the pulley.

Fig. 19[16] illustrates quite clearly how the maximum amplitude of vibration of the shaking table, which simulates Mr. Slocum's unloaded transmitter, varies with the speed of rotation of the unbalanced pulley.

It would seem then that the best measure of the value of a "vibration damper or insulator" would be its capacity to absorb or dissipate the kinetic energy of the applied forced vibrations.

To measure this capacity a wave of known kinetic energy should be applied to one side of the material under test and the surviving energy of the same wave emerging from the opposite side should be measured by suitable means. For simplicity in analysis the form of the impressed wave should be simple harmonic motion, although it may be possible to analyze the resultant record of two concurrent harmonic motions of different periods, amplitudes, and epochs, provided the period, amplitude, and phase of either one is known or is capable of independent determination.

Experiments conducted by the writer in June, 1925, at East Binghamton, N. Y., may be of some value in considering the subject of vibrations set up in

[16] See Lydik S. Jacobsen in *Bulletin*, Seismological Soc. of America, Vol. 19, No. 1, March, 1929, Fig. 16.

and transmitted through the surface of the earth at no great depth, since they show to some extent the damping effect of distance traveled, on amplitude. These tests were made to determine the increase in amplitude of vibrations in a greenhouse, due to moving the main track of the Delaware, Lackawanna and Western Railroad from a location 122 ft. away to a parallel location 80 ft. away.

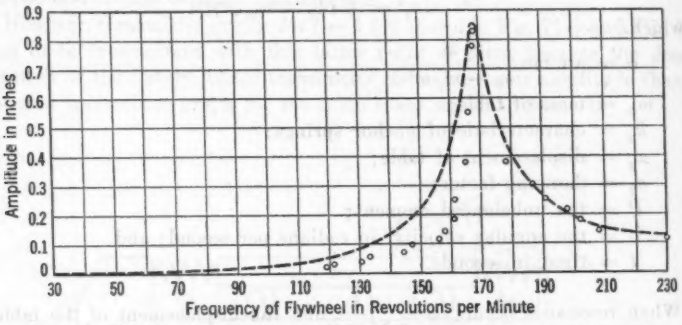

FIG. 19.—THEORETICAL CURVE FOR VISCOUS DAMPING, PROPORTIONAL TO $x'_2$ ACCORDING TO L. S. JACOBSEN.

The U. S. Topographical Survey map for this region shows the location to be at the narrowest part of the Susquehanna River Valley, the hills rising on either side of the narrow river bottom to heights of from 1 500 to 1 600 ft. The elevation of the greenhouse floor and adjoining field is 840 ft., and the normal surface of water in the river, 831 ft. above mean sea level.

This topographical layout would appear to preclude the possibility of there being any soft or yielding material underlying the sandy loam soil, mixed with the rather large pebbles on which the railroad embankment and greenhouse are situated. The probability is that it is gravelly loam, then sand, and then gravel down to hardpan, clay, and boulders mixed, and, finally, bedrock.

The instrument used in making the tests consists of a pendulum of 93.5 lb. (42.2 kg.) weight suspended by piano wire from an engineer's transit tripod. It has an undamped period of 2.222 sec., or 27 complete oscillations per min. For portability the weight is made of four accurately turned cast-iron disks, each 8¾ in. in diameter and 1¾ in. thick, mounted in two pairs on a 1-in. steel bolt which passes through an accurately bored hole in the center of each. The bolt has a taper of a few thousandths of an inch, so that each disk fits tightly. The upper pair of disks is separated ½ in. from the lower pair by three brass studs to permit two thrust arms, at right angles to each other, to be attached to the center of the steel bolt at the center of percussion of the pendulum. The entire arrangement is securely clamped together on the bolt by means of a nut countersunk in the top disk. By means of these thrust arms and a system of multiplying levers attached to the steel bedplate which is in contact with the earth, the relative motion of the earth and pendulum is magnified 148.6 times.

Record was made on smoked paper passing over a brass cylindrical drum by a fine steel needle-point in the extremity of each of the recording levers. One of the levers is bent at right angles, in order to record the two rectangular co-ordinates of motion on the same smoked sheet at a distance of 3 in. apart. To reduce the friction to a minimum all connections between thrust arms, multiplying levers, and recording levers are made either by springs or by polished conical steel pivots in V-shaped white sapphire jewels.

All moving parts are of duraluminum or aluminum. The weight of the moving parts of the amplifying lever system for one component of motion is 12⅛ grains, or about 1/3200 part of that of the pendulum.

Anticipating, from the work of Mr. Prince, of the Transit Commission in the Times Square case of the New York Subway, that the period of vibrations set up by trains would be of the order of 20 per sec., or more, all moving parts were kept as light in weight as was consistent with rigidity to resist deformation of the individual parts at high frequencies.

Record was taken of vibrations set up in the surface of the earth on the cultivated earth floor inside the greenhouse. Oak stakes 3 in. square were driven 36 in. into the ground with the tops a few inches above the surface, and the earth was thoroughly compacted about the stakes with a sledge hammer. Three "set-ups" were made, as shown in Fig. 20. The records cover the passing of fifty-eight trains of all classes—passenger, freight, milk, and combination—in both directions, east and west; and they include five days of operation.

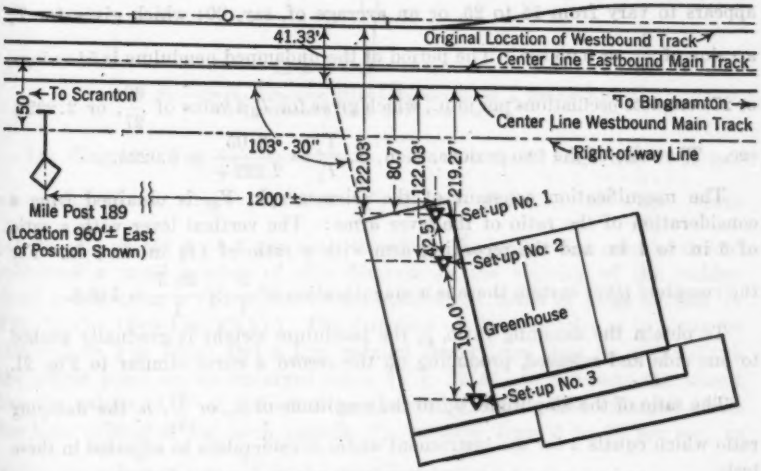

FIG. 20.—PLAN SHOWING RELATIVE POSITIONS OF TEST SET-UPS.

Set-Up No. 2 was assumed to represent the condition existing before the track was relocated; Sept-Up No. 1, the site of present maximum disturbance; and Set-Up No. 3 was located as far from No. 1 as it was possible for it to be and still remain within the greenhouse.

The method of mounting the seismograph on stakes driven in the ground was adopted to harmonize with the type of construction used for the greenhouse, which consists of a glass roof supported on iron pipe posts resting on short wooden fence posts driven in the ground flush with the surface.

The maximum amplitude recorded for each train movement at each set-up was taken, for comparison, as representing a measure of the maximum earth movement to which the column footings in that vicinity were subject.

*Interpretation and Tabulation of Results.*—In any seismograph constructed on the pendulum principle with a system of multiplying levers, the actual amplitude of the earth's motion may be calculated from the amplitude of the trace on the seismogram by means of the formula:

$$A_e = \frac{A'}{V_0}\sqrt{\left(1+\frac{T_e^2}{T_0^2}\right)^2 - 4\,\frac{\frac{T_e^2}{T_0^2}}{1+\frac{1}{\pi^2}(\log_e \rho)^2}} = \frac{A'}{V_0}\,U \qquad \ldots\ldots\ldots(7)$$

in which,

$A_e$ = the amplitude of the earth's motion from zero position;
$A'$ = the amplitude of the trace record from zero position;
$T_e$ = the period of the earth movement, in seconds;
$T_0$ = the period of the undamped pendulum of the seismograph;
$V_0$ = the magnification constant of the seismograph; and,
$\rho$ = the damping ratio.

From the records the number of complete earth vibrations per second appears to vary from 15 to 25, or an average of, say, 20; which gives for $T_e$ a value of $\frac{1}{20}$, or 0.05 sec. The period of the undamped pendulum is 54 swings, or 27 complete oscillations per min., which gives for $T_0$ a value of $\frac{60}{27}$, or 2.222+ sec. The ratio of the two periods, then, is, $\frac{T_e}{T_0} = \frac{0.05}{2.222+} = 0.0225$.

The magnification constant of the seismograph, $V_0$, is obtained from a consideration of the ratio of the lever arms: The vertical lever with a ratio of 5 in. to 1 in. and the recording arm with a ratio of 14½ in. to ½ in. For the complete lever system there is a magnification of $\frac{5}{1} \times \frac{29.7}{1} = 148.5$.

To obtain the damping ratio, $\rho$, the pendulum weight is gradually pushed to one side and released, producing on the record a curve similar to Fig. 21. The ratio of the amplitude, $y_1$, to the amplitude of $y_2$, or $\frac{y_1}{y_2}$, is the damping ratio which equals 3 for the instrument under consideration as adjusted in these tests.

A collineation diagram, Fig. 22(*a*), has been drawn by F. W. Sohon,[17] for a graphical solution of Equation (7), by which the value of the radical factor modifying the value, $\frac{A'}{V_0}$, and usually designated as $U$, may be readily

[17] See *Bulletin*, Seismological Soc. of America, Vol. XIV, No. 3, September, 1924.

obtained. This diagram consists of a circle of unit radius calibrated for the period ratio, $\frac{T_e}{T_0}$, a tangent line calibrated for values of the damping ratio, $\rho$, and a secant line calibrated for the value of the radical factor, $U$.

Laying a straight-edge from the point on the circle indicated by the ratio of $\frac{T_e}{T_0} = 0.0225$, which is very near the point of "sudden shock" at the junction of the circle with the secant line, to the point on the tangent indicated by the damping ratio of 3, the value of $U$ is read at the intersecting point on the secant line.

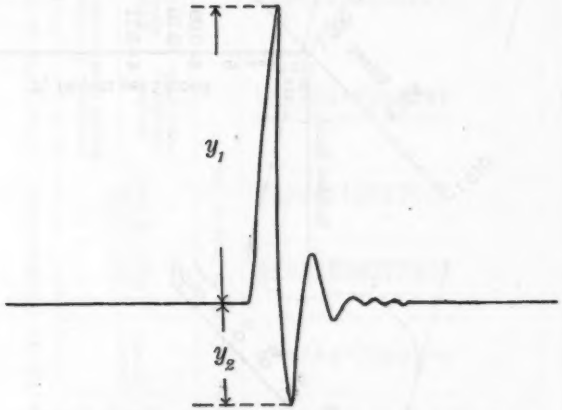

FIG. 21.—CHARACTERISTIC CURVE PRODUCED BY A PENDULUM TO DETERMINE THE DAMPING RATIO.

The diagram (Fig. 22), however, is on such a small scale that it is not convenient to use where values of $\frac{T_e}{T_0}$ are less than 0.1, or where earth periods, $T_e$, exceed 4 or 5 per sec.; therefore, the writer has computed and calibrated a small portion of this diagram in the vicinity of the sudden shock point, using a radius more than sixty-seven times as large as that in Fig. 22($a$). (See Fig. 22($b$).) The direction of the line from $u$ to $\rho$ can be obtained on Fig. 22($a$) and a line parallel thereto can then be drawn from the proper point on the enlarged circle (Fig. 22($b$)) to intersect the secant line for values of $U$ as indicated by the dashed line. The enlarged circle has been calibrated for earth periods, $T_e$, running from 3 to 25 per sec., as well as for values of $u$ or $\frac{T_e}{T_0}$ in the neighborhood of 0.1.

To show the relation of the smaller diagram, the dashed line, drawn parallel with the line from $u = 0.0225$ to $\rho = 3$, is drawn from $T_e = 20$, and cuts the secant for values of $U$ at 0.9996 or 0.0004 less than unity. This is so near to unity that the error involved in using unity is less than that

which is unavoidably involved in scaling the amplitude on the record, and this value of unity, therefore, has been used in reducing the results of the writer's tests to actual amplitude of the earth's motion.

In reducing the results of the tests, the maximum recorded double amplitude or displacement, to both sides of the zero position, shown for each train and for both horizontal components of motion, parallel with and at right angles to the track, is measured to the nearest 0.001 in. by means of a micrometer caliper gauge. The distance thus obtained is divided by 2 to get the amplitude from the zero position, and this amplitude, $A'$, divided by $V_0$, or 148.6, gives the actual amplitude of earth movement from zero position. This computation has been carried out to the fifth decimal place, the result being in hundred thousandths of an inch.

Table 1 illustrates the general arrangement of observed data obtained during these tests. Identical record numbers apply to identical trains for each set-up. For example, in Fig. 23, Record No. 8 (Table 1) refers to the amplitudes observed during the eastbound passage of the Lackawanna Railroad Passenger Train No. 6 as determined on successive days. As reproduced in the paper, the trace is magnified 119.6 times the original vibration; the magnification of the original graph was 148.5.

The maximum amplitude of earth movement from zero position, $A_e$, is found usually, but not invariably, at the time the locomotive is opposite the instrument, the maximum parallel with the track seldom occurring at the same instant as that at right angles thereto. Motion at right angles to the track is generally, but not always, considerably greater than that parallel with the track (see Table 1).

A comparison of maximum amplitudes given in Table 1 shows that the westbound trains produce a movement nearly twice that of the eastbound trains. This damping of the vibrations from the eastbound track seems to be due to the weight of the 7-ft. cinder fill, ballast, and track of the westbound main line under which the vibrations passed to reach the seismograph.

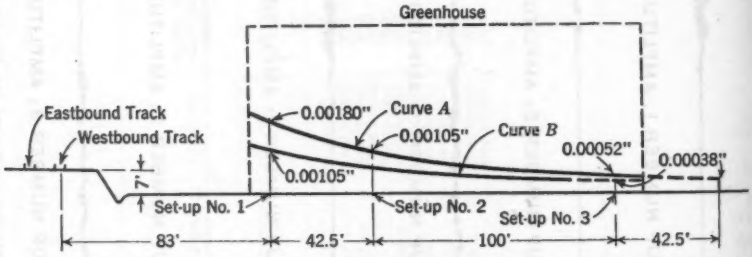

FIG. 24.—PROFILE OF OBSERVED AMPLITUDE AT RIGHT ANGLES TO THE MAIN LINE.

*Conclusion.*—In conclusion, if a profile is drawn on a line extending from the tracks through the greenhouse and passing through the three observation points (see Fig. 20), using the average of all the maximum observed amplitudes at right angles to the track at each set-up as elevations above this line, it will be possible to visualize the relation between amplitude of the earth's motion

and distance from the track. Such a profile is illustrated by Curve *A* in Fig. 24.

Due to the position of Set-Up No. 2 that portion of the profile beyond it will represent the condition as to vibration existing prior to the relocation of the main tracks 41.33 ft. closer to the greenhouse.

If this part of the profile with a northward extension of 42.5 ft., based on the indicated decrease in amplitude with distance, is moved that distance south within the first profile so that Set-Up No. 2 coincides with Set-Up No. 1, then the difference between the gradient lines of the two profiles (Curve *A* minus Curve *B*) will represent the increase in amplitude affecting the greenhouse due to the shift in position of the main tracks.

The base line of the profile makes a northeasterly angle of 103° 30′ with the center line of the westbound main track, and is parallel with the center line of the greenhouse. The distances to the several points along this line from the center line of the westbound main track are, therefore, correspondingly greater than the right-angle distances to the same points as given in Fig. 20.

A record was also taken of an Erie Railroad freight train passing on the opposite side of the Susquehanna River, at a distance of about ¼ mile from Set-Up No. 1. The maximum observed amplitude parallel with the track was 0.00013 in. and that at right angles, 0.00011 in.

Time marks on the records were spaced 10 sec. apart. The instant when the locomotive was opposite the seismograph is indicated in Fig. 23 by a free-hand mark above the record. It was observed that vibrations began from 4 to 6 sec. before this instant.

STEPHEN E. SLOCUM, M. AM. SOC. C. E. (by letter).—In the discussion of this paper by Mr. Den Hartog the point is made that there is a rational explanation of the phenomena accompanying these tests, which of course is the case. There is a wide distinction, however, between a qualitative explanation and a quantitative measurement, and in actual practice it is undeniably true that the determination of nodes, natural frequencies, etc., is, in general, best made by experiment. The idea which the writer intended to convey was that even in the simplest cases it is necessary to make certain assumptions as to uniformity of material and conditions of constraint before a numerical solution of the vibration characteristics can be attempted. In most actual structures, the constraints are so involved as to make any attempt at a theoretical solution impossible. For instance, it would seem to be a hopeless task actually to calculate the vibration characteristics of a modern rotary printing press, such as that used in printing the daily papers; or to determine by calculation at just what point in a skyscraper, and to what extent, traffic vibration would set up a synchronous disturbance.

Steel springs, mentioned by Mr. Den Hartog, can be used only in a few very special cases. The writer experimented extensively with steel springs some years ago in connection with engine mounting in automotive apparatus, and found that, to cushion the torque recoil, a very weak spring was needed, which was not stiff enough to resist road shocks; consequently, this type of mounting was found to be impractical. In railroad and street-car work, steel

springs are used to lessen the impact from road shocks which tend to set up vibration, but to dampen the residual vibration actually set up, the remedy generally adopted is to separate the non-rigid metallic contacts by the insertion of pads of resilient damping material. For the special purpose for which this research was undertaken, namely, the determination of the physical properties and vibration characteristics of damping materials suitable for use as isolation pads under grillage foundations of tall buildings, steel springs are obviously out of the question.

In Mr. Tatnall's discussion, the principal point made is that change in design is a more effective remedy for vibration than isolation. This is true only of machinery built from a stock design and operated under fixed and uniform conditions. For instance, the crank shaft of a Diesel engine should be designed so as to be free from excessive torsional vibration at the operating speed of the motor. In machinery like compressors and blowers, however, it is usually impractical to eliminate vibration by changes in design, and the only feasible method of preventing the transmission of vibration is isolation from adjacent structures.

Mr. Dawley's criticism of the author's experimental set-up would be pertinent and valuable if the experiments had been intended as a basis for mathematical analysis of the compound system, although his suggestions by no means cover all the difficulties involved. As this series of experiments was apparently the first of its kind, at least so far as published results are concerned, there were numerous fundamental questions to be answered before the problem could be stated in sufficiently exact terms to warrant an elaboration of set-up which would differentiate results more closely.

For instance, some of the primary questions involved and on which no information could be gained elsewhere, were such as the following:

(*a*) For a substance like asbestos, what effect does increasing the unit load on the material have on its properties as a vibration damper?

(*b*) For lateral insulation of footings would a mastic joint be as effective as corkboard, or if the latter was used, would a layer 4 in. or more in thickness be necessary, or would a 1-in. layer be sufficient?

(*c*) For track insulation, would a layer of sand be more effective than a layer of gravel? This question was of prime importance, since if experiment had indicated that sand was greatly superior, its use would have involved excavating a layer of natural glacial drift, easily plowed up into gravel, and replacing it with sand.

Evidently none of these problems involved a mathematical determination of nodes or harmonics.

Mr. Dawley mentions that loading the H-beam at the third point would create a node at this point. This was exactly what was intended, as the effect of applying the load from the testing machine at a node was to cut out the testing machine from the vibrating system, and to just this extent reduce the complexity of the problem.

Mr. Dawley expresses as his opinion that the best measure of a vibration damper or insulator is its capacity to "absorb" or "dissipate" the kinetic energy of vibration. As a matter of fact, no pad of whatever material either absorbs

or dissipates the energy of vibration. The only way in which this could occur would be through generating heat by molecular friction, and there is not the slightest evidence that anything of the kind occurs. The word which most fully describes a vibration damper is "isolation". The effect of such isolation is to short-circuit the vibration, reflecting a certain fraction of its energy back into the transmitting system; and to just the extent to which it is effective in reflecting the energy of vibration, it is successful in preventing its transmission to the receiving system.

To handle the vibration problem intelligently requires considerable versatility of method. In the case of machinery, the first consideration is whether change in design is possible, and if so, whether it will reduce vibration to a point where it is not objectionable. For heavy machinery, the design of the foundation is often involved in the problem. In the case of traffic vibration, the street pavement or track roadbed is an important factor to be considered. In tall buildings, an important remedy lies in isolation of the structure by various means. A notable consequence of the tests summarized in this paper was the discovery that a simple compressive pad was by no means the most effective method of applying resilient dampers. The tests also disclosed the fact that the range of damping materials commercially available is extremely limited, and that none possesses all the required properties of an effective damper or isolation medium under all conditions of use and loading.

As pointed out, vibration engineering should be a fertile field for the activities of the Society. Although there seems to be many specialists working independently in this field along such widely divergent lines as seismology in oil fields, and impact stresses in bridges, there is no attempt to co-ordinate their efforts or systematize their results. In London, England, the serious effects of traffic vibration on such notable structures as the Nelson Column, the National Gallery, in Trafalgar Square, St. Paul's Cathedral, and Westminster Abbey, has forced the question of remedying matters on the attention of the Office of Works, and this has made the question of vibration a permanent subject of research and discussion by the Science Committee of the Royal Institute of British Architects.

In Germany, the Scientific Council of the Vereins Deutscher Ingenieure took steps as early as 1923 to foster research in vibration engineering, and on December 11, 1924, that Society organized a Committee on Vibration. In order to give direction to this research, the Committee called attention to three specific problems, namely, dynamic strain in machines and structures, due to high frequency vibrations; general disturbance, such as noise and tremor due to vibration; and research in the technique of mechanical vibration, both in scientific laboratories and in industry, with the related problem of the endurance of materials of construction subject to vibration.

In 1927 this Committee on Vibration held a two-day convention at Braunschweig. The principal topics discussed at this conference were approved methods of conducting vibration experiments; laboratory methods in current use; necessary and sufficient conditions for judging the value of vibration measurements; energy absorption or damping capacity of building materials;

acoustic experiments with various materials and types of construction; structure of crystals as related to vibration endurance; and electrical apparatus for measuring the strength of sound.

In 1928, this Committee held a three-day session in Darmstadt, the principal topics considered being the fatigue of materials of construction subject to vibration; experimental measurement of vibration in railway tracks and bridges; natural modes of vibration of machine foundations; destructive effects of vibration due to street traffic as related to condition of pavement and type of tire; development of instrumental methods of measuring vibration; absorption of energy of vibration by materials of construction; and the use of annealed instead of hardened steel for machine springs.

For the first time, in the 1927 Edition of "Hütte", a well-known handbook for German engineers, a section was devoted to the subject of vibration.

Heretofore, the problem of vibration has been confined in its engineering aspects almost entirely to machine design and operation. In the United States the rapid increase in height of skyscrapers, together with a growing volume of street and subway traffic, has created a new and vital vibration problem. The rapid growth of this field in other lines, such as radio engineering and seismographic prospecting for oil on the Gulf Coast, has given a new aspect to the entire question. It has long been recognized that vibration is a basic phenomenon in physics and chemistry. It is equally apparent that it is a basic principle in many branches of technology, such as electrical engineering, sound reproduction, and geo-physics. The particular phase which commands immediate attention is the destructive effects of vibration on men and materials. In this particular line of effort, perhaps greater advances have been made in this country than elsewhere, but it still remains for American engineers to co-ordinate this accumulated knowledge and to systematize the principles of vibration control into a specialized branch of engineering. The Society is the obvious agency for this purpose.

# PAST EXPERIENCE WITH HIGH DAMS AND OUTLOOK FOR THE FUTURE

By A. J. Wiley,[2] M. Am. Soc. C. E.

## Synopsis

This is a brief account of past practice in the design of high dams, with comments that indicate that the higher dams of the future will be of a solid masonry gravity type, either arched or straight. As between a straight gravity dam and a dam of the same section arched in plan, preference is given to the latter, or the so-called "arched gravity dam".

Between an arched gravity dam in which—because of the preponderance of gravity action—the arch stresses are low, and a less-than-gravity section arch in which the arch action predominates, preference is given the arched gravity type. Reasons for the writer's belief that the arched gravity dam is more stable than a straight gravity dam of the same section are given in the paper. Furthermore, some suggestions for the design of future high dams are offered for consideration.

## Comparison of Types

Dams can be divided into two classes, the earth embankment type and the masonry type. In the former the material is devoid of strength and prevents the passage of water only by the sum of the resistances of its individual particles. In the latter the inherent strength of the masonry forms an impenetrable barrier to the water. The strength of the earth embankment types is not subject to definite analysis. The mass is always greatly in excess of that required to resist the static pressure of the water, and is determined largely by previous experience as necessary to prevent percolation or seepage.

In the masonry types only a very small part of the mass is needed for watertightness and stability is subject to close analysis and mathematical determination.

Ordinary earth is probably less subject to the agencies that cause disintegration and decay than any other material of construction, and within its limits, the earth-fill dam is probably the most enduring of all types. The limiting condition of the earth dam and of its types—the hydraulic-fill and the rock-fill—is in the difficulty of making it impenetrable to water and in preventing its saturation and consequent instability. Experience up to the present indicates that earth embankments, hydraulic fills, and rock fills, although admirably adapted to many conditions for heights as great as 200 or 300 ft., are not likely to be adopted for dams of really great heights and large volumes of storage.

[2] Cons. Hydr. Engr., Boise, Idaho.

Masonry dams have no such limiting conditions and can be safely designed for any height likely to be needed in the future. On the other hand, masonry dams have one very rigid limiting condition from which earth dams are free; that is, the necessity of hard and durable rock foundations. This is particularly true of arched dams which require not only very hard foundations, but may need even harder abutments, because the arch thrust may be greater than the cantilever reaction.

*Dams of Masonry.*—Since their introduction masonry dams have always been given the preference for structures of great height, but the application of scientific principles to design only dates back to the development of the gravity type of masonry dam in about 1855.

The first high gravity dams were straight in plan and were built of stone masonry laid in hydraulic lime mortar. Prior to 1870 it was assumed that uplift could not act on the base, and no allowance was made for it in the design of these dams; nor was any attempt made either to reduce or prevent it.

The design of high dams since about 1910 has been influenced by the practically complete replacement of stone masonry by concrete, and by the rapid extension of the use of reinforced concrete. There has thus been developed at about the same time (1) the arched gravity dam of comparatively long radius; (2) various types of arch dams of shorter radius and less-than-gravity section; (3) multiple-arch dams; (4) buttress type, or Ambursen dams; and (5), the multiple-dome dam.

Gravity dams have been either straight or arched. It would probably be correct to state that the use of arched gravity dams has been largely confined to the Western States, and that this is due to the more rugged topography which gives deep and narrow canyons where high dams of short radius can be used.

*Arched Gravity Dams.*—In the design of arched gravity dams the same cross-section is used as in a straight gravity type, on the assumption that the reduction in gravity action, due to the convergency of the radii, would be more than offset by horizontal arch action. In the earlier designs of arched gravity dams the same practice of ignoring uplift was followed as had been the custom in straight gravity dams. Many important dams of the arched gravity type—such as the Cheesman Dam, 235 ft. high, and the Roosevelt Dam, 280 ft. high—were built on this theory. These two dams were not only among the last high, arched, gravity dams to be built of stone masonry, but they were about the last in which no attempt was made to provide for uplift in the design or to remove it.

In nearly all the arched gravity dams built of concrete, uplift is reduced by deep cut-off trenches at the up-stream face, and by pressure grouting and drainage of the foundation. Uplift in the body of the dam is guarded against by vertical drains near the up-stream face. Examples of this type are the Arrowrock Dam, 350 ft. high above the foundation and 260 ft. above the stream bed; the Don Pedro Dam, 278 ft. above the stream bed; the Exchequer Dam, 325 ft. above the stream bed; the Lancha Plana Dam, 350 ft. high; and the Owyhee Dam, which will have a height of 325 ft. above the stream bed, and 405 ft. above the foundation.

In all these and in many other dams of similar design, the convergency of the radii is assumed to be offset by arch action and the uplift reduced, by pressure grouting and drainage, to an amount which can be taken care of by arch action.

*High Arched Dams.*—At the same time as the arched gravity dams, various types of less-than-gravity arch dams with shorter radii, were being built in narrow canyon sites. The arched dams have been either of fixed radius, variable radius, or variable radius with constant-angle types.

In arched dams of constant radius the section is a reduced gravity type with the up-stream face vertical. The aim is to reduce the vertical tension and compression in the up-stream and down-stream faces to a minimum on the assumption that tension in the one and excessive compression in the other will be avoided as in the full gravity section dam.

In the variable radius designs the aim is to carry the greatest possible part of the load on the arch, although the tendency of this is to increase the vertical tension and compression at the faces. The variable radius with constant angle, or the "constant angle arch", is a variable radius type in which the volume is reduced to the minimum by maintaining a constant central angle of about 120 degrees.

Examples of the fixed radius type are: The Shoshone Dam, 250 ft. above the stream bed and 330 ft. above the foundation, with a base of 142 ft.; the Salmon River Dam, 220 ft. high, with a base of 101 ft.; the Warmsprings Dam of the overflow type, 100 ft. high, with a base of 27 ft.; the Gibraltar Dam, 185 ft. high, with a base of 65 ft.; and the Melones Dam, of the overflow type, 200 ft. high and 85 ft. thick at the base.

An example of the variable radius type is the Gibson Dam, 195 ft. high, with a base of 87 ft. Many dams of the variable radius or constant angle type have also been built, including the Kerchoff (overflow) Dam, 105 ft. high, with a base of 36 ft.; the Salmon Creek Dam, 168 ft. high, with a base of 38 ft.; the Cushman Dam, 280 ft. high, with a base of 52 ft.; and the Pacoima Dam, recently completed, which is 375 ft. high, with a base of 96 ft.

The principle of the multiple-arch dam is very old, but the present type, with inclined up-stream face, has been developed since about 1910. Examples of multiple-arch dams are the Gem Lake Dam, 112 ft. high; the Lake Hodges Dam, 136 ft. high; the Florence Lake Dam, 160 ft. high; the Palmdale Dam, 175 ft. high; and the Tirso Dam, in Italy, 239 ft. above the foundations.

*Multiple Dome Dam.*—The multiple dome dam is a new type of which the only example is the Coolidge Dam on the Gila River, in Arizona. It may be described as a multiple-arch dam with great length of span and very massive piers. By thickening these piers toward the base the arch radius is shortened progressively from the top to the bottom of the dam. The arches as well as the piers are very massive so that the thin construction of the multiple-arch type is avoided.

The Coolidge Dam is 250 ft. high and consists of three arches and two piers, the sides of the canyon forming the buttress for the arches at each end of the dam.

*Ambursen Type Dams.*—In the Ambursen dam, the arches connecting the piers or buttresses of the multiple-arch type are replaced by reinforced concrete

flat slabs or beams. Many dams of this type have been built since about 1905. The latest are the Stony Gorge, 120 ft. above the stream bed, and the Rodriquez Dam, 140 ft. above the stream bed and 200 ft. above the foundations, which is now (1928) under construction.

*Higher Dams of the Future.*—The highest dam yet undertaken is the Owyhee Dam (now under construction), which is 405 ft. high above the regular foundations and 520 ft. above the deepest point of cut-off. The San Gabriel Dam, 500 ft. high, is now under construction. The Boulder Canyon Dam, 700 ft. high above the foundations, is now authorized for construction.

The San Gabriel Dam is arched to a 1 400-ft. radius and is of a gravity design with an increased section to allow for convergence of the radii. The Owyhee Dam is of the arched gravity type with a 500-ft. radius and no increase of section to allow for convergence of radii.

There will be, no doubt, a constant improvement in the design of all types of dams and an increase in the height to which they can safely be built, but at present the arched gravity type of masonry dam is slightly in the lead with respect to height.

## Selection of Type

*Arch vs. Straight Section.*—In places where an arch of such a radius as will give any degree of arch action can be used, it should always be given the preference over a straight dam of the same section. The length of radius that will give useful arch action is subject to wide differences of opinion. It is the writer's view that, assuming the construction to be done in such a way as to give vertical joints practically free from leakage, an arch of any required radius is preferable to a straight dam. This is based on the fact that if there are no open joints extending entirely through it, the slightest deflection of the dam as a gravity cantilever will cause an equal deflection in the horizontal arch and a division of the load in some proportion between the cantilever and the arch.

If there are open joints extending through the dam, that are watertight at the down-stream face as assumed, then there is a reduction of the water pressure on the up-stream face from the back pressure on the joints. To the writer there seems to be a culpable waste in not utilizing as much as possible the horizontal compressive strength of the concrete in the arch, along with its vertical compressive strength in the cantilever.

*Arched Gravity Type.*—As between an arched gravity dam and an arched dam of considerably less than gravity section and correspondingly shorter radius, preference in the case of a very high dam should always be given to the arched gravity type. In the case of the arched gravity dam there is a massive section capable of carrying the full load by its weight alone and, in addition, there is the resistance of the massive horizontal arch. For a less-than-gravity arch, regardless of the type, the load is carried primarily by a more or less highly stressed arch, with the certainty that if the arch should fail the vertical cantilever would also fail.

*Stability of Arched Gravity Dams.*—Many of the highest dams in the world are of the arched gravity type. Still higher dams of this type are under construction, and others even higher are proposed for the immediate future.

In one arched gravity dam investigated by the writer, no contraction joints had been provided. Contraction cracks on nearly vertical radial planes were formed, and a small amount of seepage was in evidence at the down-stream face. Water under reservoir pressure applied to the crack through a drill hole intersecting it at a depth of 10 ft. in from the surface, increased the seeped area, but the same pressure applied to the crack at 20 ft. from the face had no effect whatever upon the seepage.

In the great majority of arched gravity dams with which the writer is familiar, there never has been any indication of moisture at the vertical joints. There are others, not provided with joints, which have cracked on vertical radial planes, but which have never seeped at the cracks, or elsewhere. There are other arched gravity dams in which there are occasional spots in a vertical joint where seepage and even leakage appears, but these are rare and cover an insignificant fraction of the total number of joints.

The use of metal seals in the contraction joints near the up-stream face would not prevent the access of reservoir pressure to any open seams in the dam from which there is no leakage. It is the writer's observation that every void or seam in a masonry dam is filled with water under pressure. This was shown by the water which seeped out of the body of the St. Francis Dam for weeks after the failure. This seepage was apparently from the body of the concrete and was not confined to joints or seams.

It is interesting in this connection to note that dams in India, excellently constructed of rubble masonry laid in hydraulic lime mortar, are entirely free from cracks although they are straight in plan, but that the water seems to filter through them so freely that it oozes from the entire down-stream face which is completely covered with a film of water as if from a fine spray. This is only a temporary condition, however, and the dams soon become free from visible seepage.

An arched gravity dam of short radius is more stable than one of longer radius. For example, consider the extreme case in which the up-stream radius is equal to the thickness of the dam at a given elevation. The horizontal section would be triangular, and if the water pressure is to be confined to the up-stream face there will be no open joints and there will be arch action. If there are open joints, thus preventing arch action, the pressure at the up-stream face would be reduced by the back pressure on the planes of the joints, the summation of which would equal the area at the up-stream face, so that at the section at which the radius is equal to the thickness, if there are open joints, there would be no unbalanced water pressure at all to be resisted by the dam.

It follows from this that in an arched gravity dam assumed as being free from arch action by reason of open joints, as the radius of curvature is shortened, the stability is increased by the reduction of the effective water pressure.

In the special case of a dam without vertical joints, and in which the tensile strength of the concrete is greater than the contraction stress, there would be no cracks. In this case there would be tension in the arch and the effective pressure area would be that of the up-stream face. This would cause tension in the vertical cantilever, but it is reasonable to conclude that there would be the same resisting tensile strength in the concrete in a vertical direction as is

assumed in a horizontal direction. This condition, moreover, would be avoided by the common practice of providing contraction joints at regular intervals.

Even if the existence of open joints is admitted, if the correct assumption of the effective pressure area is made, arch action can be neglected and an analysis which takes into consideration the reduction of section by convergence of the radii will show no tention in the up-stream face of an arched gravity section designed as a straight gravity dam with the lines of pressure at the middle-third points. Such an analysis will show that arch action is always present in an arched gravity dam, giving it a greater degree of security than from a straight gravity dam of the same section.

*Uplift In and Under Dams.*—Examination shows that the concrete in the St. Francis Dam was practically free from horizontal joints or seams. In a very few cases the concrete had been given a smooth surface on a horizontal joint and apparently had been allowed to set before new concrete was put on top of it. In such cases there seemed to be no union at all between the new concrete and the old.

On the other hand, concrete applied to a hard rock surface seems to become an integral part of the rock. The mica schist bed-rock adhered to the bottom of one of the overturned sections of the St. Francis Dam so firmly that the hard rock could be broken more easily than its union with the concrete. Drill cores from the bed-rock contact at many points of the Mulholland Dam showed a union of the concrete and the sandstone foundation apparently as strong as either the rock or the concrete. If, in placing concrete, care is taken to avoid "cold joints" by chipping away the surfaces which have set in air before placing the new concrete upon the set surfaces, it will be possible to avoid all horizontal joints both in the concrete and in its connection to a hard rock foundation.

The absence of stress due to uplift in the body of the concrete appears from the consideration that the water can act only in the voids. The pressure in a void in the concrete is in all directions, and, considering only the vertical pressures in a single void, it might appear that a tensile stress in the concrete would result; but considering that the upward and downward forces in each void are opposed and cancelled by equal downward and upward forces in the voids immediately above and below, it is readily seen that the summation of the vertical forces in the voids is zero, and that no vertical stress in the concrete can result from water pressure in the voids. This has also been shown by the application of enormous pressures to a liquid without effect upon the concrete or other porous substance immersed in it.

The uplift conditions appear to be the same at the junction with the bed-rock as in the body of the concrete, and it may be concluded that there is no uplift in the body of a homogeneous mass of concrete, or in a rock that is free from seams, or in a perfect contact between rock and concrete.

In the case of an open horizontal joint in the concrete or a horizontal seam in the rock, there is uplift for which allowance should be made in the designs of a straight dam, although in many, if not most, straight gravity dams, no such allowance has been made.

When the bed-rock is seamy and there are springs in the foundation, the possibility of uplift should never be ignored in a gravity type of dam, although certainly less provision need be made in an arched gravity than in a straight gravity dam.

*Seepage from Dams.*—Nearly all the high concrete dams built recently have been provided with an open gallery constructed in the concrete close to the foundation and to the up-stream face. Closely spaced wells drilled into the bed-rock discharge upward into this gallery and vertical drains paralleling the up-stream face of the dam discharge downward into it. There is a discharge from the wells and drains and usually also from seams in the concrete. The extent of this seepage varies with the character of the rock, and with the height and area of the water face exposed to reservoir pressure. There is less seepage from the softer shale or sandstone rocks and more from the harder granitic or dioritic rocks. The seepage from long high dams is much greater than from lesser dams and, as the rate of seepage is a function of the area of the dam face above the stream bed and also of the height, the ratio of seepage should vary with the three-halves power of the height.

Seepage water from dams usually carries lime in solution as calcium hydrate, which on exposure to air is converted into calcium carbonate. Calcium hydrate is always present in concrete, where it is formed by release from the cement in the reactions due to the process of setting. Seepage through new concrete usually ceases after a few months by the filling of its voids or by the sealing of its discharge by the deposit of calcium carbonate at or near the outer surface.

If water seeping through a seam in the concrete continues to deposit calcium carbonate without sealing the seam, there may be deterioration of the concrete and enlargement of the seam. All seepage of water carrying calcium hydrate in the galleries of a dam should be stopped by persistent caulking and pressure grouting.

The value of metal stops in contraction joints is open to question. Arched dams without such stops have proved to be perfectly free from seepage at the vertical joints. It is the writer's experience that there is never any trouble in preventing water from following the vertical construction or contraction joints in an arched dam. Even the most casual treatment of the vertical faces of such joints, by building one face against alternate shallow grooves and ridges formed in the other, is adequate; but it is extremely difficult to prevent seepage along horizontal "day's-work" joints if the previous layer has been allowed to set. It is necessary to provide the horizontal joints with many ridges or grooves in the concrete parallel to the axis, to clean the old surface thoroughly, and to prime it with mortar in advance of the concrete. With all these precautions there are occasionally seepages and unsightly stains at horizontal joints.

The utility and desirability of the vertical drains usually placed close to the up-stream face of concrete dams are questionable. They are supposed to reduce the percolation of water in the concrete and thus diminish uplift, and also to prevent the appearance of moisture at the down-stream face. Examination of several dams in which the vertical drains were omitted, shows them to be as dry as others under like conditions in which they were used. It would

seem desirable to prevent the seepage of water through a dam by increasing the density of the concrete and the distance which the seeping water has to travel, and to avoid the use of any device which offers a short travel for the escape of water, either through the body of the concrete or through its seams or joints.

The use of sand cement is sometimes recommended as reducing the cost and decreasing the permeability of concrete, but it should never be used in a locality where frost action is possible. In one important dam, in a moderately cold winter climate, the use of sand cement has resulted in serious disintegration of the concrete wherever it is exposed to moisture and to winter temperature, although adjacent parts of the structure made of Portland cement concrete are entirely unaffected. The writer would always avoid the use of sand cement except possibly in a warm dry climate.

A very substantial economy in concrete for massive dam construction can be made by the use of large-sized gravel or cobbles. The cobbles are run through the mixer in measured proportions with the other aggregates. The first use of cobbles in concrete was at the Arrowrock Dam, where the maximum diameter was 5 in., but they have been used in gradually increasing sizes up to 8 in., or more, on the Don Pedro and Exchequer Dams. This use of cobbles in the proportion of about 25% of the volume reduces the cement without reducing the strength or the imperviousness of the concrete.

It has been shown that seepage at the down-stream face of contraction joints is usually caused by water flowing through open cracks or joints near the top where the dam is so thin as to be affected by temperature. For this reason, as well as for other conditions of design, it is desirable to make the top of the dam much thicker than stability requires, and a thickness of 30 to 40 ft. for very high dams is not too much.

*Pressure Grouting of Contraction Joints.*—The writer has considered herein only the case of dams in which no attempt has been made to increase the tightness of the joints by pressure grouting. In the writer's opinion pressure grouting would result only in the filling of the joints for a distance of 15 to 20 ft. inside the faces of the dam, and this would not appreciably increase the arch action in a massive arched gravity dam.

## Conclusions

From the foregoing, the writer presents the following conclusions:

1.—Masonry dams on suitable bed-rock are safe and permanent structures and are most suitable for very high dams.

2.—An arched gravity type of masonry dam, whether built of concrete or of rock laid in mortar, has a larger factor of safety than a straight gravity dam of the same section.

3.—The contraction joints of an arched gravity dam do not prevent arch action.

4.—If the contraction joints should open so as to prevent arch action, water entering the joints would reduce, by its back pressure, the effective head on the dam and compensate for the loss of arch action.

5.—The stability of an arched gravity dam is increased as the radius of curvature is shortened.

6.—There is no uplift in the body of a concrete dam except that caused by horizontal joints, nor in foundation rock which is free from seams, nor in a perfect connection between the dam and the bed-rock, except that which may be due to a different degree of porosity in the concrete and the rock.

7.—Seepage through concrete may be detrimental and should be remedied by pressure-grouting, or by other means.

8.—The use of sand cement in cold climates should never be permitted.

# CLASSIFICATION, SELECTION, AND ADAPTATION OF HIGH DAMS

By D. C. Henny,[3] M. Am. Soc. C. E.

## Synopsis

In this paper the tendency to build dams of ever-increasing height is indicated. Foundation requirements for various types of dam are discussed; conditions limiting height are analyzed; and sources of danger are considered.

## Historical Sketch

The progress in the design and construction of high earth dams during the Twentieth Century may be illustrated by reference to a report made in 1901 by an eminent Engineering Commission on changes in the New Croton Dam and the Jerome Park Reservoir of the New York Water Supply, which were then under construction.[4] The problem as to the New Croton Dam involved the safety of the earth dam portion as planned.

After investigating other earth dams, of the New York Water Supply, the Commission concluded that, with the material available, a dam higher than 70 ft. would not be safe. It recommended substituting solid masonry for earth in the high part of the dam, and that recommendation was approved by the authorities although it resulted in great additional cost.

This recommendation came as a surprise to engineers on the Pacific Coast, who were familiar with the Pilarcitos and San Andreas Dams, near San Francisco, Calif., and the Temescal and San Leandro Dams, near Oakland, Calif., all of which had been in successful service for twenty-five years at that time. Their respective heights are 95, 125, 115, and 125 ft. above stream bed.

The conclusion reached by the Commission was based principally on the fact that the water gradients in the other earth dams of the New York Water Supply System were found to intersect the down-stream slope high above the toe. The late Alphonse Fteley, Past-President, Am. Soc. C. E., then Chief Engineer of the Croton Aqueduct, questioned the correctness of the conclusion and, in the published discussions, drainage of the lower toe was mentioned as a means of lowering the plane of saturation.

## Examples of High Dams

With a more complete understanding of the effect of such drainage and of selection or segregation of materials, engineers did not hesitate to build dams of ever-increasing height, so that the list of earth dams as high as 100 to 150 ft. has become a long one. The highest earth dam built to date is the Tieton Dam, in Washington, which is 233 ft. above stream bed. The Cobble Mountain Dam, in Massachusetts will be 245 ft. high.

[3] Cons. Engr., Portland, Ore.

[4] *Engineering News*, November 25, 1901.

The same evolution as to height is proceeding with all other types of dam. Among rock-fill dams may be mentioned the Morena Dam, in California (215 ft.), and especially the Dix River Dam, in Kentucky (275 ft. high), completed, respectively, in 1909 and 1925. The Pacific Gas and Electric Company is now (1928) building a rock-fill dam 300 ft. high on the Mokelumne River in California.

As to masonry dams of the gravity type, the straight Elephant Butte Dam, in New Mexico, is 240 ft., and the curved Arrowrock Dam, in Idaho, is 251 ft. above stream bed, with a height above the base of 308 and 349 ft., respectively. Both were completed in 1916 and held the record for some time, with the straight Kensico Dam, in New York (307 ft.), as a close third. These records have been broken by the Exchequer and Pardee Dams, in California, respectively, 330 and 350 ft. above the base; the former was completed in 1926 and the latter in 1929.

The Owyhee Dam, in Oregon, and the San Gabriel Dam, in California (the former of the arch gravity and the latter of the gravity arched type), will be 405 and about 490 ft. above the base, respectively. These heights, in turn, will be exceeded by the Boulder Canyon Dam, in Arizona-Nevada, which may reach a height above the base of 680 ft.

Examples of the single arch type of great height are the Shoshone Dam, in Wyoming, 320 ft. (1910), the Pacoima Dam, in California, 375 ft. (1928), and the Diablo Dam, in Washington, now under construction, to be 400 ft. above the base.

The same tendency toward greater height is shown in the buttress type of dam which includes the multiple-arch, Ambursen, round-head buttress, and dome forms of dams. The Lake Pleasant (multiple-arch) Dam, in Arizona, is 256 ft. high. The Rodriquez (Ambursen) Dam, in Lower California, Mexico, will be 225 ft. high. The Don Martin (round-head buttress) Dam, in Northern Mexico, a type suggested by F. A. Noetzli, M. Am. Soc. C. E., is 118 ft., and the Coolidge (dome) Dam, in Arizona, is 250 ft. high.

Among high dams on other continents are the Burring Juick (gravity) Dam, in Australia, 244 ft.; the Montejaque (arch) Dam, in Spain, 270 ft.; and the Tirso (multiple-arch) Dam, in Italy, 239 ft. above the base.

Questions arise as to whether the tendency to build dams of ever-increasing height will reach some definite limit beyond which it is not safe to go and what elements are likely to limit the heights of various types of dam.

## Dam Foundations

The foundation problem is at all times the most difficult, because in spite of elaborate geological study and underground exploration it is, in its nature, the most obscure; yet on it must mainly depend the selection of type and ultimate safety. Theoretically, it may be contended that a foundation is rarely so poor as to render the construction of some type of safe dam upon it impossible. Assuming the reservoir bed to have a sufficient degree of watertightness, defects of dam foundation can be overcome in general by a combination of type selection, deep penetration, and foundation treatment. Lack of hardness may dictate the adoption of a flexible type and a broad spread-

ing of load and lack of tightness may compel the selection of a type with wide base, enforcing sufficient length of underground water travel. The complete rejection of a dam site is usually based, however, on economical considerations.

## Earth Dams

Given a foundation free from such uncertain materials as quicksand and layers of marshy soil, and assuming the presence of the usual kinds of earth materials for construction—which, in themselves, or by segregation or mixing, can be made to supply earth of reasonable tightness for the up-stream part and material with free drainage qualities for the down-stream part—it is believed that no limit can be assigned to the safe height of earth dams, assuming the maximum height of water against them to be definitely controlled. Even in the case of some clay foundations which, when wet, may have small load resistance and when loaded may produce lateral pressures, safety can be obtained by proper proportioning of slopes and top width.

Lateral foundation movement may be absent in a low dam, but may take place in a high dam of the same proportions. Such movement took place in the Summer Lake Dam, in Eastern Oregon, a structure about 60 ft. high, of ordinary earth-dam proportions founded on clay. It settled, cracked, and forced the down-stream river bottom to rise about 3 ft. This was corrected by rebuilding to a flatter down-stream slope. An instance of settling occurred at the Lafayette Dam, near Oakland, Calif., which when it had reached 122 ft. of its ultimate 140 ft. of height above the stream bed, settled 20 ft. and produced a rise of ground under the lightly loaded toes. An engineering board has recommended less height and flatter slopes if this dam is reconstructed.

These instances illustrate the great difficulty of correct slope adjustment to wet clay foundation, but do not prove that a dam of great height cannot be built safely on such foundation.

## Rock-Fill Dams

The rock-fill dams, which usually have steeper slopes than the earth dams, require foundations and building material of greater compressive strength. Furthermore, because of the high percentage of voids they require material which is free from weathering and water-softening so as to avoid excessive and, at times perhaps, sudden settlement and destructive bulging of the face slab. Any defect in this respect cannot be fully cured by the adoption of flatter slopes and, therefore, it imposes a limit on height. Greater height also may induce increase in volume of seepage and, therefore, requires greater resistance to erosion along areas through which the seepage may proceed. The greater base pressure of reservoir water also necessitates a higher degree of water-tightness of foundation material, the distance around the tight skin from full reservoir pressure to no pressure being far shorter than is available in an earth dam with broad contact.

Thus, it is held that local conditions impose a limit on the height of rock-fill dams to a degree far greater than is the case with earth dams. On the other hand, it is likewise held that with a hard and durable rock base,

not subject to water-softening, with similar character of rock available for building and with a base water-tight, or capable of being made so by deep grouting, no reason exists for assigning a limit of height to this type of dam, short of that resulting from hardness of the building rock.

The combined earth and rock-fill type is a special adaptation of the earth dam. It may be superior to the common earth dam in cases where the latter has material of unsatisfactory drainage quality in its down-stream part, but requires a harder foundation to support the loose rock portion unless this is placed on a prepared foundation of the inverted filter type. It may also have advantages over the face-slab rock-fill type where broader contact for water-tightness is required with the foundation or where rock settlement is anticipated such as might endanger the effectiveness of a concrete face slab. In past examples of this type, as, for instance, the Twin Falls Dam, in Idaho, it has happened that percolation water has carried earth into the loose rock interstices, causing craters to form in the water slope accompanied by heavy loss of water. However, even in such cases, no serious danger to the dam has usually been involved, and it has been possible to stop flow by emergency measures. Such occurrences can be readily prevented by the interposition of a layer of crushed rock or gravel between earth and rock. It is believed that, with suitable foundation and building materials, dams of great height can be built in this type with fewer demands on tightness of foundation or hardness of rock than would be essential in the case of face-slab dams. All rock-fill types, however, as well as the earth dam, must be fully protected from overflow, as is illustrated by the failure of the first Lower Otay Dam.

### Masonry Dams

The term, "masonry", is herein understood to include both stone masonry and concrete. For economic reasons concrete has almost completely displaced other classes of masonry in this country. The same tendency exists abroad.

Due to their rigidity masonry dams make far greater demands on foundation strength than the relatively flexible earth and rock-fill dams. In the latter, foundation loading changes gradually from the middle to the toes. In the former, it changes abruptly from maximum to zero.

In the gravity type of dam the load at the heel is almost solely governed by the height and the weight of the masonry and that at the toe, in addition, by the down-stream slope. The strength of the foundation rock is, therefore, likely to limit the safe height of a gravity dam within a far narrower range than is the case with a loose rock-fill dam. This, however, does not mean that dams of far greater height than those of the past cannot be built safely, but merely that requirements of hardness of foundation increase approximately in proportion to the height of the dam.

The same is true of the required strength of the building material which in past construction has probably never been stressed more than 600 or 700 lb. per sq. in. in compression. Concrete with a known strength of 3 000, 4 000 and even 5 000 lb. per sq. in. in 28 days is now readily secured, and there seems to be no reason why concrete in the base of a dam could not be safely subjected to compressive stresses of 1 000 lb. per sq. in., or even more (such

as would obtain in a dam about 630 ft. in height), provided a source of satisfactory aggregate is at hand and the proper mix is used.

With increase of height, other requirements, such as water-tightness of foundation and of structure, rise correspondingly; so, also, do the demands on the drainage system under and in the dam. As far as the structure is concerned, these demands can probably be met by increased use of cement in the concrete and special care in bonding. Improvement of the foundation is least under control and the nature of the foundation is, therefore, the element most likely to fix the safe limit of height.

The buttress type of dam with its sloping face can be designed so as to tax the foundation to a lesser extent than necessarily results from the gravity type, despite the apparent concentration of load on the buttress bases. The resultant of dead and live load can be made to fall close to the center of gravity of the bearing area of the buttress, the proportions of which can be adjusted to local conditions, and maximum loads can be kept down, if desired, to little more than one-half those in pure gravity dams. The sliding factor can also be held down more readily than in gravity dams and the demands on foundation tightness are no greater, while the danger from uplift is much less. The dimensions of the web between the buttresses, whether arch, slab, or round-head, can be adjusted to the stresses. Thus, the strength and tightness of foundation rock place a closer limit on the height of the gravity than of the buttress type.

Arch action may be called to the aid of gravity dam support under a wide range of dimensions of dam sites. However, the single arch dam with nearly vertical axis is limited in its application to sites which permit the use of relatively short radii. With a given radius the arch pressure can be held below a desired limit, but secondary stresses are not so readily controlled. This is especially true of tension and compression stresses at the base. The introduction of steel where needed and of horizontal expansion joints at the up-stream toe forming a hinge, as was done by the writer in a dam constructed for the water supply of Ashland, Ore., or the adoption of the dome principle, as suggested and developed by C. R. Olberg, M. Am. Soc. C. E., and carried out in the Coolidge Dam, or a curved base support as was proposed years ago in the Ithaca Dam by Gardner S. Williams, M. Am. Soc. C. E., may in part solve this difficulty.

Arch dams make greater demands on the foundation in the abutments than the gravity dam, because a slight yielding under load has a profound effect on arch stresses. With a proper foundation the height of such dam will be largely controlled by the radius or radii to which it must be built.

Material progress has been made in the design of arch dams, recently aided by the results obtained from the Stevenson Creek Test Dam and tests with models, as sponsored by Engineering Foundation.[5] One valuable result has been the indication that deflections under various conditions of loading can be foretold with considerable accuracy by model tests. This will not only permit closer determination of stresses, but will also increase confidence in the correctness of design and in the safety of high arch dams.

### Flood Danger

Dams blocking the discharge from large drainage areas are subject to potential danger and damage from flood overflow during construction.

It is often possible to complete a low earth or rock-fill dam above the base, or that portion of a higher dam left open for safe flood passage, within a season between floods. When this cannot be done and sufficient by-pass capacity cannot be feasibly provided, risk from overflow during construction must be taken, and this risk becomes greater with increasing height and volume of dams. If this risk cannot be assumed, seasonal measures must be taken for permitting safe overflow as, for instance, through a temporary flume over the down-stream slope of the dam, as was provided in the building of the hydraulic-fill dam near Conconully, Wash., or by paving the down-stream section with concrete as was done in the Nexaca Dam, in Mexico.

The consideration of floods may impose a severe restriction on the height of earth and rock-fill dams. The difficulty of estimating maximum floods is well understood as is also the danger of under-estimates which have been the cause of several major disasters in the past. Presumably with these considerations in view, Italy, by governmental regulation, has limited the height of earth dams to 20 m. (66 ft.) and of rock-fill dams to 25 m. (82 ft.).

It is probable that some earth dams standing in the path of flood discharge from large drainage areas and now deemed safe because of assumed sufficiency of spillway capacity, are in actual danger from flood overflow and, in places where great height and especially large storage are involved, public interest may demand immediate attention.

In the case of masonry dams danger from overflow during construction, even when no apron has been provided, is usually not great. The uncompleted structure has excessive strength to resist water load and would usually be stable even after a serious undermining of the toe due to overflow erosion. Attack on the foundation is generally most serious along the abutment toes where a lateral current may be set up. Therefore, it seems wise to confine emergency overflow to the central part of the dam unless special apron protection is provided along the slopes.

The arch form of dam renders the safety of the structure less dependent on the preservation of rock integrity below the toe than is the case with the straight gravity dam. Uncertainty as to maximum flood flow may be in some cases a sufficient argument for incurring additional expense, which may be involved in curving gravity dams.

### Earthquake and Earth Movement Danger

The danger of earthquake and earth movement is a serious factor in the selection of type and, in fact, in deciding whether any type of high dam can be safely built, especially on the Pacific Coast. The scrupulous search for a possible fault crossing the dam site and the geologic estimation of the occurrence of last movement along such fault, therefore, have become common practice.

Very severe earthquake shocks may be borne safely by straight gravity dams and earth dams, as well as by pure arch dams. This was well illustrated by the undamaged condition of the straight concrete Crystal Springs Dam and the earth San Andreas Dam after the 1906 earthquake in San Francisco and of the pure arch Gibraltar Dam after the Santa Barbara earthquake in 1925. Since the gravity dam depends on its dead weight for safety and not on the continued integrity of the entire structure, as is the case with an arch, it is probably more secure from earthquake damage. The earth dam is liable to be overtopped by a tidal wave and, on the whole, the gravity dam must be regarded as the safest, especially if curvature in plan gives it additional safety against sliding and if its cross-section has been determined on the basis of converging radii and of possible uplift. These considerations led to the selection of the arched gravity type instead of the more economical arch for the East Park Dam in Northern California completed after the San Francisco earthquake.

If a dam must be located across a fault line the gravity type has distinct advantages, because even if sheared, its parts would probably otherwise remain in place and oppose their mass to a rapid release of stored water. The semi-flexible Ambursen dam with buttresses straddling the fault may also be regarded as safe, at least against minor earth movement along the fault line, and this type was selected in preference to the multiple arch for the 120-ft. Stony Gorge Dam, in Northern California, which crosses a fault.

The ordinary earth dam is unsafe if it crosses a fault line along which movement may take place. This was evidenced after the San Francisco earthquake in 1906 by the condition of the first or Upper Crystal Springs Dam, which crosses the San Andreas fault. The body of the dam was found to be badly fissured, both laterally and longitudinally, and it would have been destroyed had not the water stood at the same height on both sides of the dam, owing to the backing up of reservoir water by the Crystal Springs (concrete) Dam below.

### Cracking of Concrete

Another and possibly serious danger in cases where mass concrete is used in the construction of high masonry dams (which is now usual in the United States for economic reasons) is the tendency of concrete to crack after dissipation of internal heat.

When concrete sets, its temperature is raised and it will expand until compressive strength develops and expansion meets with resistance. Further heating will set up compression. Subsequent cooling will reduce compression until it is completely neutralized, after which further cooling tends to produce tensile stresses. Increase of load will tend to reduce these stresses, whereas drying out of the concrete will tend to increase them. The existence of shrinkage cracks in many concrete dams shows that the tensile stresses exceeded the tensile strength of the concrete. This is not surprising when it is considered that a heating of concrete to 30° Fahr. and more is not uncommon, and that a cooling of 15° is likely to produce a tension of more than 150 lb. per sq. in.

Cracks will naturally show first on the sides of large dam blocks having the longest horizontal dimension and where air cooling and possibly drying have induced tension. These cracks may penetrate only a short distance into the concrete and may tend to close, after the lapse of time, as the interior mass cools. With further interior cooling the outer concrete that previously cracked under tension, by interior pull, may be placed under compression, and this interior pull may become intensified until previous skin cracks extend partly or wholly through the mass.

In concrete dams, the thickness or base length of buttresses increases with height, and the tendency to crack becomes aggravated by the greater internal heat generation due to higher cement content and relatively smaller radiating surface. In gravity dams, the tendency to crack in a transverse direction has usually been counteracted by the provision of contraction joints even if transverse shrinkage cracks approximately normal to the axis of the dam contain no element of danger. Cracks parallel to the axis of the dam, whether in the mass of a gravity dam, or in the buttresses of a buttress dam, may be of serious consequence, especially as such cracks are likely to be approximately vertical and are thus often close to the direction of maximum shear. The presence of such cracks may well become equivalent to a dangerous narrowing of the base. In buttresses, it is generally feasible to introduce sufficient temperature steel to prevent them, as was done, for instance, in the case of the Stony Gorge (Ambursen) Dam, in California, where, in the early stage of construction, such cracks became evident. In gravity dams, prevention of shrinkage cracks by the use of steel would be enormously expensive.

In the buttresses of the Coolidge Dam and the 165-ft. Big Dalton (multiple-arch) Dam near Los Angeles, Calif. (both completed in 1929), contraction joints parallel to the axis of the dam and to the direction of the principal stresses have been introduced. The same provision has been made in the design of the San Gabriel (arched gravity) Dam now under construction near Los Angeles.

In addition, the forming of shrinkage cracks may be counteracted partly by a suitable construction progress program. Such a program may prohibit over-rapid construction and may require each concrete layer to remain exposed with the surface kept moist for a specified length of time to effect maximum cooling. It may reduce the height of rise from 5 or 4½ ft., which has become usual, to 4 ft., or even less. Under extreme conditions it may call for pre-cooling of the mixing water and aggregates. It may also specify that each step of the work be brought up level or nearly level from end to end. In this way expansion of fresh concrete, as it heats and acquires compressive strength, will meet with early resistance from adjoining concrete, and subsequent cooling must first cause compression to be neutralized before tension can develop.

## Uplift

The possible dangerous effect of uplift either at or below the base of gravity dams or higher up in the concrete mass has been long known. It may re-distribute loading in an injurious way and in all cases it increases the tendency to slide.

In modern dam design provisions are made to reduce or prevent uplift, such as a deep cut-off wall with or without a grouting curtain and a system of drainage. In addition, allowance for uplift is generally made in the design, but great differences of opinion exist, not merely as to the pressure gradient to be assumed (in regard to which valuable experimental data are being accumulated), but especially as to the proportionate area over which this pressure may be considered effective. Attempts at experimental determination undertaken recently at the Bull Run Dam have yielded negative results because water-creep through construction joints in mass concrete seems to be due to unavoidable imperfections of actual work which cannot be duplicated in the laboratory. Generous allowance for uplift in the design, strenuous efforts to obtain water-tightness and perfect bond, together with ample and effective provisions for drainage, are the only safeguards which have been developed thus far independent of measures to increase the resistance to sliding, such as enlarged thickness and curving the dam in plan.

The design manifestly should aim at opposing the movement of water through the up-stream part of the dam and facilitating it after this barrier has been once passed. From this point of view keys in contraction and construction joints in the down-stream part of the dam are objectionable.

Construction joints are planes of weakness both for sliding and for penetration of water which may exert uplift. It is an advantage, therefore, to avoid the usual horizontal joints and to require joints to curve upward in a down-stream direction, so as to become normal to the dry slope as nearly as ordinary concrete deposition will permit. In this manner, the incidental advantage of reduction of maximum shear in construction joints will be secured.

### Tension in Foundation

Finally, attention must be called in the case of masonry and, especially gravity, dams to the possibility of tension in the foundation rock near the heel. This matter was ably discussed[6] by Messrs. Ottley and Brightmore in 1908. The subject was treated by them both theoretically and experimentally. The tension under a full head of 30 in. in the model was calculated and for a shape of ordinary proportions was found to be about 1.2 lb. per sq. in., which for a height of 400 ft. would be equivalent to about 200 lb. per sq. in. The direction of maximum tension was also calculated and the existence of such tension and its computed direction were confirmed by cracks in the plasticine models.

The serious feature of such tension lies in the fact that it increases with the height of the dam; that the direction of possible cracks or the widening of existing rock fissures is such as to extend from the heel downward under the dam; and that the opening thus formed may cross the assumed vertical zone of foundation tightness, whether natural or procured by grouting. By such opening direct communication may be established between open reservoir and the foundation drainage system which may be overtaxed thereby, with the possible result of increased uplift and erosive seepage.

[6] *Minutes of Proceedings*, Inst. C. E., Paper W-3674, Vol. CLXXII, 1907–08, Pt. II, p. 89.

It is true that the effect of such cracks has not been observed in actual dams, but nevertheless cracks may exist and they may become more pronounced in dams of greater height. The danger may be counteracted to some extent by spreading the base of the dam in an up-stream direction and introducing steel as was done in the case of the Bull Run Dam, even if this dam is not of unprecedented height and the base rock is strong and remarkably free from fissures. The same measures are specified for the San Gabriel Dam with the added precaution (understood to be common in Germany) of placing a triangular body of plastic clay along the up-stream toe.

## Conclusion

A heavy responsibility rests on the shoulders of engineers engaged in the design and construction of dams of ever-increasing height. Information which may assist in avoiding danger is being accumulated in many directions.

# HIGH DAMS: THE VIEWPOINT OF THE GEOLOGIST

By F. L. Ransome,[7] Esq.

## Introduction

If rocks were entirely homogeneous it would probably rarely, if ever, be necessary to call upon a geologist to examine a site for a high dam. It could safely be assumed by the engineers that the rock exposed at the site continues unchanged in horizontal and downward directions, and that consequently the appropriate tests for strength, imperviousness, and other properties, applied to samples from the site, would determine whether a dam could safely be constructed at that locality. At first thought, the necessity for considering the effect of earthquakes might be regarded as an exception to the foregoing general statement, but serious earthquakes are a consequence of movement along faults, and faults are obviously departures from homogeneity.

As a matter of fact, rocks are never perfectly homogeneous for any considerable distance. The nearest approach to the ideal is probably to be found in large intrusive masses of rock that have solidified from a molten condition, at great depth, and have been exposed at the surface only after long erosion. These are the plutonic rocks, which are of interest to the geologist, and of which granite is the most familiar example. Even in granite, however, it is necessary to reckon with the possible existence of faults; with various types of fractures; with zones of crushing or shearing; with included masses of other rock, such as schist; with later dikes of different kinds; and with contacts between the granite and other rocks.

In layered rocks of many sorts, the lack of homogeneity is more obvious. A compact lava flow, of basalt for example, may be spongy or vesicular in its upper and lower parts, or may rest on a layer of conglomerate or of loose lapilli. A bed of hard sandstone may be succeeded by a bed of soft, soluble gypsum, or even of rock salt. A stratum of limestone may be overlain by a layer of shale. An upturned bed of quartzite may be separated by a belt of slate from a belt of mica schist, etc., in almost infinite variety. These relations, moreover, may be further complicated by igneous intrusions and by faulting.

It is in the recognition and interpretation of such departures from homogeneity that the chief usefulness of the geologists in relation to dam sites lies. Such essential elements in the geological structure may not be apparent at the actual site and yet may constitute vital factors in its proper selection. To recognize them and to grasp their significance in relation to a proposed dam is likely to require a knowledge of the region such as can be acquired only by geological methods of investigation and by geological experience.

Clearly, the fundamental requisites in the rocks at a site for a high dam are: (1) That the rocks be strong enough to withstand the stresses transmitted

[7] Prof. of Economic Geology, California Inst. of Technology, Pasadena, Calif.

from the structure; (2) that they be reasonably impervious; (3) that they neither change in volume, nor soften, nor dissolve, under the action of water; and (4) that they be not subject to such movement as would damage or destroy the structure. It is proposed, in what follows, to consider the relation of various rocks and geological structures to these fundamental requisites.

## Geological Requirements for a Reservoir

A geological investigation in connection with a proposed dam site commonly comprises two parts—that of the reservoir as a whole and that of the actual dam site.

Failure of a reservoir, where the dam remains intact, is rarely catastrophic. It may, however, mean the loss of valuable water, or such large leakage that the reservoir becomes wholly useless. Hardness or strength is seldom an important consideration in the rocks of the reservoir as a whole. Even porous rocks, provided that the open spaces are not connected so as to form continuous channels, need cause no concern. Freely permeable rocks and soluble rocks, however, require particular attention and must be considered in relation to the geological structure of the region. Examples of freely permeable rocks are beds of gravel or poorly cemented conglomerate and some volcanic tuffs or breccias. Basaltic lava flows may be so frothy or cavernous, particularly near the top and bottom of each flow, as to permit the passage of large volumes of water. Ordinary compact limestone, although its solubility under normal conditions and for such periods as need be considered in engineering practice is usually negligible, is nevertheless geologically soluble, as is plainly shown by the occurrence of such great caverns as those near Carlsbad, N. Mex., and the familiar underground streams of some limestone regions. Consequently, in places where a proposed reservoir is to be partly or wholly on limestone, it becomes necessary to determine, if possible, whether there are any existing caverns or subterranean chambers through which the water might escape.

Wherever freely permeable rocks occur in a reservoir site a knowledge of geological structure becomes highly important. Clearly, for example, a permeable bed which outcrops in the reservoir and, by maintaining a regular dip, appears again along the banks of a stream a few miles distant at a lower elevation, would conduct water away from the proposed reservoir, whereas, if the permeable bed is dislocated by a fault, or folded so that there is no hydraulic gradient to any lower outcrop, it might not permit any serious leakage.

Where permeable rocks are present, the position and slopes of the underground water surface, or water-table, should be ascertained. In most drainage basins, the water-table practically coincides with the topographic surface near the streams and rises toward the ridge crests, although at a more gradual slope than the surface of the ground. Such a condition indicates that the underground water of the basin is moving slowly toward the streams that drain the basin, and, consequently, that the proposed reservoir will be more likely to receive than to lose water by underground flow. On the other hand, if the water-table in some part of the basin is found to be lower than at the adjacent streamways, this indicates that some water is escaping from the basin through

underground channels and, consequently, that still more might escape were the basin converted into a reservoir. Obviously, in a reservoir formed merely for flood control, such loss would be immaterial and might even be advantageous.

Among the soluble rocks most likely to require attention in reservoir projects are gypsum and rock salt. The McMillan Reservoir, near Carlsbad, is partly a failure because the water escapes in large quantity through underground channels in gypsum and these are increasing in size. On the other hand, Willow Lake, another reservoir about 20 miles south of Carlsbad, is enclosed by gypsum, but has shown no leakage since the dam was built, about 1922. The difference is probably to be explained by the supposition that, in the case of the McMillan Reservoir, there was initially a small natural solution channel through the gypsum, which the water enlarged rapidly by further solution, whereas, at Willow Lake, no such passage exists and, although gypsum is going into solution everywhere around its shore, this general solution has not led to any leakage. Rock salt is, of course, even less trustworthy than gypsum as a water barrier. Thick beds of salt occur in the proposed Boulder Canyon Reservoir, along the Virgin River, Nevada, but their position is such that they cannot cause leakage. The question that has been raised as to whether these salt beds would render the water of the proposed reservoir too saline for use, is a reasonable one, and indicates a possibility that should not be overlooked. In this particular case the effect of solution would be to blanket the salt with silt from overlying beds and the quantity of salt dissolved would probably be negligible in so large a body of changing water.

### Significance of Topography at a Dam Site

As the purpose of most high dams is to impound as much water as is practicable behind a structure of minimum size and cost, the site is usually a narrow canyon above which the stream flows through a valley or basin. The existence of a steep-walled, narrow canyon generally indicates that the rock at the canyon is harder than that in the up-stream valley. This indication, and the fact that canyons are geologically youthful features, determine the favorable condition that the rocks in canyon walls are as a rule well exposed and relatively fresh, particularly near and under the stream. It is often comparatively easy, therefore, to ascertain the character and structure of the rocks in the canyon and to recognize transverse faults, if they are present. These faults are the generally favorable features of a canyon location.

It is advisable, however, to determine why a stream forsakes an apparently easier course (as is frequently the case) and turns aside to cut a canyon through hard rock. It is particularly important to ascertain whether this apparent preference is due to a fault or other particular line of weakness along the canyon and concealed by the sand, gravel, and boulders of the present stream bed. This may be a complex geological problem requiring an understanding of the development of the topography of the region. The river may have had its course determined by rocks and structures that have been completely removed by erosion and, having once cut into the formerly buried, harder rock, has been forced to remain within it. In this case, there would be

no reason to expect the existence of a line of weakness under the stream bed. On the other hand, some smaller stream, with more direct path to the sea and steeper gradient than the main river, may have captured the larger stream by head-water erosion. If so, there may be a belt of weak rock under the bottom of the canyon. As a rule, the courses of faults are more nearly rectilinear than the courses of streams. Consequently, the presence or absence of a fault along the bottom of a canyon can usually be determined by an examination of spurs and ridges that extend across the prolongation of a line drawn through the part of the canyon at the dam site. For example, at the site of the Owyhee Dam in Eastern Oregon, the drill records suggested the presence of a fault under the river. Examination of the ground showed a little ravine and saddle, in line with the gorge, and the suggestion was made that a trench be dug across this ravine with a view to exposing the fault zone. The fault was found, as expected, and provisions to deal with it were embodied in the design of the dam.

### The Element of Initial Strength in the Rocks at the Dam Site

It may fairly be assumed that the rocks at a dam site should be at least as strong as the material of which the dam is to be built. Ordinarily, this means at least as strong as good concrete. The actual strength of sound samples of the rock can readily be determined by the usual engineering tests. It is for the geologist, however, to point out the bearing of geological structure on the strength of the rock mass as a whole. For example, a site may be in granite which shows a crushing strength of 25 000 lb. per sq. in. and yet the presence of zones of shattering or shearing may make the site unsafe for a high dam.

In stratified rocks, the attitude of the beds must be taken into consideration. As every quarryman and mason knows, stratified rocks are stronger in directions perpendicular to the bedding planes. Ordinarily, an up-stream dip of the beds would appear to be more favorable to dam construction than a down-stream dip. Yet, with beds of different degrees of permeability, conditions might exist that would make a down-stream dip preferable. In beds that are nearly horizontal, or in steeply inclined beds, striking approximately parallel with the stream, the possibility of the slipping of one bed past another can not be ignored.

This last consideration applies particularly to shales and to slates and schists. The St. Francis Dam is believed to have failed first at its northwestern abutment, but the southeastern abutment was of little better quality. The dam at that end was built against schist in which the thin laminations stood nearly parallel with the slope of the canyon wall. The concrete was poured against the smooth cleavage faces of the schist and adhered to them, but there was little more adherence between the schist laminations themselves than between the sheets of a pile of paper.

Joints in rocks have a bearing on the strength of the mass, but they are also important with reference to permeability and will be considered more fully under that subject.

Without going further into detail, it is sufficient to emphasize the fact that, as regards the initial strength of the rocks at a dam site, it appears to

be the particular function of the geologist to call the attention of the engineers to the effect of structural features which may not be obvious to them, but which can be recognized by those who have had special training in geological observation and interpretation.

### The Element of Permeability in the Rocks of a Dam Site

In considering the behavior of rocks with respect to leakage around a dam, it is necessary to distinguish between porous and permeable rocks. Certain volcanic rocks, such as vesicular basalt, or more or less pumiceous rhyolite, may be eminently porous, but yet, because of the lack of connection between individual pores or cavities, these rocks may be relatively impervious.

As it is the essential function of a dam to retain water, leakage is to be avoided where possible. Nevertheless, there is a wide range between permissible or controllable leakage and conditions under which the escaping water is a serious loss or endangers the entire structure. The slow seepage of water through a porous but insoluble rock, such as a spongy lava, may cause no important loss from the reservoir; it is more likely to decrease than to increase, and can do no harm. On the other hand, even a small leakage through rocks that are partly soluble may enlarge the original openings, or, by removing the cementing constituents, so weaken the foundations of the dam as to cause disaster.

When a dam is built on stratified rocks it is important to know the stratigraphic section in detail and to consider each different kind of rock with reference to possible leakage and the effect of such leakage.

Fractures in the rocks may be classed as faults and joints. A fault is a fracture of considerable horizontal and vertical persistency, along which the rock on one side has moved past the rock on the other. The displacement may be a few inches or several miles. A characteristic feature of a fault is a seam of clay-like material, known as gouge, which has been produced by the grinding together of the rock walls during the movement on the fault. The seam of gouge may range from a fraction of an inch to 8 ft., or more, in thickness. It is ordinarily accompanied on one side, or on both sides, by a zone of shattered or crushed rock. The gouge is usually impervious, but the shattered rock is likely to be freely permeable. Consequently, faults, where present, must be considered as probable paths of leakage. A fault, it is important to note, cannot be removed by excavation. If nearly vertical, it may be expected to continue far below the bottom of the dam and, if nearly horizontal, far beyond the dam, in all directions.

Joints are relatively short fractures along which there has been no appreciable movement of one side of the crack past the other. Consequently, they contain no gouge. They are present in most rocks, and, when long exposed to the weather, as in canyon walls, they may become superficially accentuated and give such an alarming appearance of general fragility to the rock mass as has led some engineers and geologists to an unjustified condemnation of particular sites.

The fine-grained granitic rocks of Boulder Canyon, on the Colorado River, are dissected in many places by innumerable joints. Yet short tunnels driven

into some of the most thoroughly jointed rock have shown that within 10 to 20 ft. from the surface the joints become scarcely visible and the blocks into which the granite is divided are so irregular in form and so tightly fitted together that no important leakage could take place. As granite is practically insoluble and unaffected by water, no material could be removed, and, in a practical sense, the presence of the joints is negligible. Moreover, joints in hard, insoluble rock, if they are open enough to cause serious leakage, are amenable to grouting.

### The Effects of Solubility in the Rocks at a Dam Site

Solubility is, of course, a relative term. Probably no rock is completely insoluble under all conditions found in Nature. The solution of rocks like granite, quartzite, and basalt, however, is so slow or so slight as to be practically negligible. On the other hand, rock-salt and gypsum are dissolved so rapidly in flowing water as to make them utterly unfit for the foundation of a high dam. Limestone and marble occupy an intermediate position between these two groups. That limestone is geologically soluble, especially in water containing carbon dioxide, has already been pointed out. Yet, with proper precautions against leakage, it would be practically safe to build a high dam on compact limestone.

The fact that calcite or calcium carbonate is the most common cementing material in ordinary sandstones and conglomerates lends particular importance to the question of the solubility of this substance. Many such sandstones and conglomerates are fairly resistant to weathering and stand out from the surface in bold outcrops. Nevertheless, the questions may be asked—Are such rocks, with a calcareous cement, suitable for the foundation of a high dam? Will water, seeping through the rock under pressure, dissolve enough of the calcium carbonate to weaken the rock seriously or to destroy its coherence? Quantitative data to answer these questions are apparently lacking, and this deficiency offers an opportunity for some experimental engineering research on the subject. In the meantime, the opinion may be offered that with good contact between the concrete of a high dam and a reasonably hard and well-cemented sandstone or conglomerate, there need be no apprehension that enough of the calcite binding material will be removed to weaken the rock appreciably, especially as reservoir waters, as a rule, do not contain much carbon dioxide in solution. In the presence of carbon dioxide, calcium carbonate goes into solution as calcium bi-carbonate, but is deposited again as carbonate when the carbon dioxide escapes or is driven off, as in the familiar example of the incrustation in the bottom of a tea-kettle. Calcium carbonate, therefore, although taken into solution at one place in the rock may be deposited in another place, close by. In this respect it differs from gypsum, which is carried away in a more persistent state of solution.

*The Action of Water on Concrete Dams.*—It apparently is not uncommon to find that water, passing through the concrete, deposits in inspection galleries or on the under side of the concrete slabs of dams of the Ambursen type, an incrustation that consists chiefly of calcium carbonate. The question has been raised: Does this calcium carbonate represent merely free and unessential

lime, leached from the concrete, or does it indicate a loss of some constituents to which the cement owes its binding power, and, consequently, a deterioration in the strength of the concrete? As far as the writer has yet been able to learn, there has been no thorough investigation of this important question. There appears to be an opportunity, therefore, for co-operative research on the subject on the part of the cement manufacturers, the National engineering organizations, and the U. S. Bureau of Standards.

It is suggested that it would be advisable, also, to investigate the solvent action of water on clastic rocks—that is, rocks composed of fragments held together by some natural cementing material. With findings based on such an investigation a standard method of testing such rocks might be devised, with a view to predicting their behavior under the action of water at various pressures.

In some localities gypsum occurs as a cementing material in sandstone. If there is any possibility of the presence of the mineral in this rôle at a proposed dam site, the rock should be carefully tested. A gypsiferous sandstone can not be regarded as a safe foundation for a dam.

### Softening or Disintegration of Rocks in Water

Some clastic rocks, particularly those held together by films of clay, may be fairly hard when dry, but become soft and plastic when wet. This change is sometimes so pronounced as to be rather startling, even to an experienced geologist. The quantity of clay requisite to produce this effect is not necessarily large. It may be a mere film at the contacts of the constituent rock particles.

Probably the most tragic and impressive illustration of the importance of recognizing this property when present in the rocks of a dam site was furnished by the failure of the St. Francis Dam, in 1928. The northwest abutment was on conglomerate, belonging probably to the Sespe formation, of supposedly Oligocene age. The conglomerate, probably a fresh-water deposit, is composed of poorly assorted schist, granite, and sandstone detritus, which ranges from clayey silt to pebbles 8 in., or more, in length. The bedding is generally rather indistinct and much of the formation is covered with soil.

When dry the conglomerate is fairly firm, although it is by no means a strong rock. A test gave a crushing strength of 500 lb. per sq. in., whereas the concrete of the dam has a strength of 2 000 lb. per sq. in. When wet, however, the rock shows a remarkable change. A piece of the conglomerate, when placed in a beaker of water, begins to flake and crumble and soon slumps to the bottom of the vessel as a loose gritty sediment that can be stirred about with the finger. Evidently, the particles of the conglomerate are held together merely by the films of clay and when the mass is wet all cohesion is lost. Even the fractured and faulted pebbles fall apart into small fragments.

The conglomerate is also traversed by many small veinlets of gypsum and it is probable that this mineral constitutes a part of the cement that holds the rock together when dry. The solubility of gypsum is well known, and the presence of this mineral probably contributes to the rapid disintegration of the mass when wet.

Obviously, a simple immersion test would have revealed the utter unsuitability of this material for the foundation of a high dam.

Other rocks, particularly some soft sandstones, show a decrease in strength when wet, although the change is not often so pronounced as in the conglomerate described. For example, specimens of the soft, massive sandstone from the Glenn Canyon site, near Lees Ferry, Ariz., show a decided softening when soaked in water.

It is the part of prudence to subject any clastic rock to an immersion test before accepting it as a safe foundation for a dam. Care should be taken, however, to obtain a fair sample and to avoid any previous loosening of the material by shock, such as might easily result from blasting.

Some fault gouges, although soft and plastic when wet, are fairly hard when dry. It is necessary to keep this point in mind when conclusions as to the possibility of recent movement along a fault are based on the character of the gouge.

### Changes in Volume of Rocks

The possibility of a change in volume in the rocks at a dam site rarely requires practical consideration. Clays, as is well known, shrink or swell with variations in the water content and anhydrous calcium sulfate or anhydrite increases in volume when it takes up water to form gypsum. These materials, however, are to be avoided in a site for a high concrete dam, on other grounds than that of possible volume changes.

Serpentine results from a slow change, involving hydration, from basic igneous rocks of the peridotite group. This alteration is accompanied by change of volume and by movement within the mass recorded by irregular shearing and smooth curved surfaces of slipping. The general unsuitability of such rock for the foundation of a high dam is due rather to the consequences of an alteration that has already taken place than to the possibility that serpentinization is a process that is sufficiently rapid or active to produce changes in the rock during the existence of the dam.

### Stability as Affected by Fault Movements and Earthquakes

A fault, once initiated, is likely to continue to be a plane of weakness and may show recurrent movements separated by long periods of quiescence. For example, there is strong evidence for the conclusion that the great Verde Fault in the Jerome District, Arizona, after a throw of 2 400 ft. in pre-Cambrian time, remained immobile throughout Paleozoic and Mesozoic time, but was active in late Tertiary or Quaternary time, with an additional throw of 1 600 ft., or a total of 4 000 ft. Renewal of movement, after long periods of rest, also took place in some faults in the Grand Canyon region of Arizona.[3]

In some faults, as may be observed in Boulder and Black Canyons, on the Colorado, the gouge has become lithified and is now a fairly hard rock. It appears safe to conclude that movement on such faults has not taken place for hundreds or thousands of years. Confirmation of this conclusion, as regards the faults in Black Canyon, was found in the fact that at one place on the

[3] See *Science*, Vol. 27, pp. 667-669, 1908.

brink, about 600 ft. above the river, smooth, water-worn channels were found in the rock, accompanied by pot-holes and river boulders. These channels could have been worn only at a time prior to the cutting of the present gorge. As one of the channels passes smoothly over one of the faults, it is clear that the fault has not moved since the river began to cut its present gorge.

In faults with soft clay gorges, it is usually difficult to estimate the probability of renewed movement in the future. An examination of historical records and of the topography may give some clue as to the recency of movements in the past and may supply some basis for a prediction as to the future. Faults with soft gouges, however, are uncertain features and should be avoided at a dam site, where this is practicable. The mere presence of a fault does not justify the condemnation of a site. It is important, however, that its existence be known, that the probability of future movement be carefully considered, and that the dam be designed to meet future contingencies, so far as this may be possible. Of course, no dam should be built across a fault known to have been active in recent times.

Mere proximity to a known zone of active faulting does not necessarily imply serious danger to a high dam. Such dams are usually of concrete and are founded on solid rock. It is re-assuring to remember that the Crystal Springs (concrete) Dam, near San Mateo, Calif., was not injured by movement on the San Andreas fault in 1906, although the fault line passes only about 900 ft. west of the dam.

Major earthquakes are usually a consequence of fault movement and the two phenomena must be considered together in relation to their effects on dams. Earthquake waves have been divided into two general classes: (1) Condensational and distortional waves, propagated with high velocity, as a consequence of the elastic property of rock; and (2), waves visible at the surface of the ground as slowly traveling undulations.

Waves of the first group rarely exceed an amplitude of 0.5 mm., although in one Japanese earthquake an amplitude of 76 mm. (about 3 in.) is recorded.[9] The origin of the slow visible undulations of the second class is not fully understood. Such waves may be 0.3 m., or more, in height and 10 m. from crest to crest. They are apparently produced by the passage of the elastic waves from rock into loose, unconsolidated material, such as alluvium. There is no satisfactory evidence that these large waves traverse solid rock and the nature of this material would seem to preclude such an occurrence.

In considering the possible effect of an earthquake on a dam, it is well to remember that a properly constructed high dam is built on solid rock and becomes in fact an integral part of the rock upon which it rests. Such a structure probably would be affected only by the short elastic waves that are propagated with high velocity through rock and not by the visible secondary waves that pass as terrifying and destructive undulations through alluvium or artificially filled ground. It is permissible, therefore, in a region subject to earthquakes, to examine the natural rock forms and to deduce from their condition the probable effect of future earthquakes on a concrete dam. This reasoning was applied to the proposed dam site at Angostura de Teras, Sonora,

[9] "A Manual of Seismology," by C. Davison, Cambridge, 1921, p. 38.

Mexico. This region is known to have experienced a severe earthquake in 1887, in which some lives were lost and damage was done to buildings in at least two small towns or villages.

In comparison with other regions of similar topography and climate, but not known to be subject to earthquakes, the rocks in the vicinity of Angostura de Teras are not exceptionally broken or shattered, and the cliffs show no more than the normal quantity of rock débris at their bases. Particularly significant in such a comparison is the Angostura de Vallecitos, a very narrow gorge in rhyolite, a few kilometers east of the dam site. The walls of this gorge are practically vertical; in places they overhang, and are at least 70 m. high. It would appear that any shock capable of destroying or seriously injuring a concrete dam would have shaken down these walls. An even more reassuring exhibit in the vicinity of the site is a slender residual spire of conglomerate, about 35 m. high, which obviously passed unscathed through the earthquake of 1887.

In a region where such relatively instable rock forms as those just cited have survived the only severe earthquake recorded in historical times, it is reasonable to conclude that a well-constructed concrete dam, founded on solid rock, and situated in a canyon, would not be damaged by a future shock of equal intensity.

In conclusion, it may be remarked that dam sites which, from the geological point of view, are ideal in all respects are exceedingly rare, if any exist. On the other hand, it is a tribute (perhaps not unduly optimistic), to the skill of modern engineers to state that a dam may be built successfully on any site, if the geological conditions are known, and if no limit is placed on cost. In practice, the construction of a dam involves compromise and adjustment between these two extremes. The one great point to be emphasized is that engineers should have before them as complete and reliable a presentation of the geological conditions as it is possible to obtain. That lesson, no one who has seen the ruins of the St. Francis Dam is ever likely to forget.

# CONSTRUCTION METHODS AND PLANT LAYOUT AT COOLIDGE DAM, IN ARIZONA

By J. G. Tripp,[10] M. Am. Soc. C. E.

## Introduction

In planning his procedure for building the Coolidge Dam on the San Carlos Project, Arizona, the contractor was faced with unusual difficulties as to plant selection and the choice of handling methods. There were three main groups of problems involved in laying out the construction plant: (1) Concrete; (2), excavation; and (3) general service problems that applied to both excavation and concrete.

Problems relating to the concrete plant involved the selection of chutes, towers, bunkers, mixers, "aggremeters", cables, anchors, steel fenders, cutters, carpenter shop machinery, and many special small tools required in the construction of the dam.

Excavation problems included the choosing and arrangement of equipment necessary to control the Gila River during construction; to excavate and dispose of 300 000 yd. of rock and 50 000 yd. of sand, gravel, and boulders at the dam site; to load and transport the concrete aggregates; and to build construction roads, etc.

In the third group was included the plant and equipment that served the general needs of both concrete and excavation activities. It involved the construction and equipment of shops for mechanical repairs and for blacksmithing, welding, rigging, etc. It also included the erection of cableways and the establishment of systems for electric power distribution, flood lighting, telephone and signal communication, water supply, compressed air supply, garbage disposal, sanitation, etc.

The selection of plant machinery was guided by careful attention to the following factors: (1) The shape of the canyon floor and walls; (2) the general topography of the dam site; (3) the total quantities involved; (4) the element of speed in construction; (5) specification limitations; (6) the kind and the cost of labor available; (7) the "construction symmetry" of the design; (8) the kind of power available—whether electric, steam, Diesel, gas, etc.—and the cost of power; (9) relative economies and first costs; (10) operating and probable salvage value of the plant; (11) transportation facilities, including space available at the site, freight rates, probability of floods, and climatic hazards in general; and (12) general economic considerations.

It is conceded that the constructor must make a profit in order to remain in business, and, therefore, a strong undertone of economy must influence his judgment in the selection of his operating plant. Equipment with a probable life equal to or less than the length of the job must be selected on the basis of first cost. Other equipment must be purchased with consideration as to its possible use on other work as well as its final salvage value.

[10] Contr., Los Angeles, Calif.

## Layout of the Concrete Plant

Since the Coolidge Dam is located in a "box" canyon (see Fig. 1), the constructor was forced to choose between two possible layouts for his concrete plant; that is, it could be established in the river bed or on the hillside.

*General Considerations.*—The latter was chosen because the Government had constructed an ingress highway along the top and because the Gila River was known as a dangerous, "flashy" stream. Any of the construction plant placed in the river bed would be subject to damage and possible annihilation by floods.

There was only one location available for storing aggregates and this was ½ mile down stream from the dam. There were three possible ways of transporting this material to the site: By road or railroad running close to the side walls along the bottom of the canyon; by motor trucks on a long, serpentine, up grade; and by means of an aerial tramway.

By choosing the latter, the flood hazard and the cost of difficult hauling by trucks were eliminated. Furthermore, the operating economy of the aerial tramway overbalanced the first cost and made this system appear as the most desirable.

*Distribution of Concrete.*—After these general selections had been made it became necessary to locate, in detail, all the various units of the concrete plant, giving due weight, one by one, to each of the eleven factors previously mentioned. Since the shape of the canyon is boxlike with sharp walls, and the width of the river bed is nearly equal to the length of the crest of the dam, it was evident that any distributing plant would have to be placed so as to reach out along the axis fully as far at the bottom of the canyon as at the level of the crest. The shape of the structure was such that its length along the axis of the stream was approximately equal to its width across the canyon at the bottom. This forced the designers of the distributing plant to consider ways and means of reaching every part of the area at the base of the dam. If the canyon had been V-shaped, with a constricted waterway, the type of plant necessary for distributing concrete at the bottom would have been very simple.

At the top, the dam recedes more than 200 ft. from its up-stream contact at the foundation. Therefore, at the river foundation, the selection of the plant was dependent on the shape of the structure. In Fig. 3, the "coverages" or the areas covered by the various chutes are shaded. Considerable thought was given to provide flexibility so that the constructor could place concrete at points widely separated between the up-stream and the down-stream limits at the base and at the top.

*Construction Symmetry.*—After analyzing the plans carefully, the constructor found that one type of plant would be satisfactory for building the lower and middle parts of the dam, but would be of little practical use at the top of the dam. The solution of this problem involved a consideration of Factor (6), "Construction Symmetry of the Design".

It was decided to pour the massive parts of the dam with one type of plant and the thin sections with another. This involved an added expense due to the first cost of the extra equipment, but the type of plant selected for the

FIG. 1.—VIEW OF COOLIDGE DAM FROM POINT 300 FEET ABOVE THE CREST, JANUARY 19, 1929.

FIG. 2.—VIEW OF COOLIDGE DAM LOOKING UP STREAM, APRIL 14, 1928.

top work had some features that created economies which partly offset this handicap. Analysis of the plans showed that it was possible to place 2 000 yd. of concrete per day in many of the lower courses, whereas in some places at the top, it would be impossible to pour more than 100 yd. per day. One type of plant could not be operated economically under both these conditions.

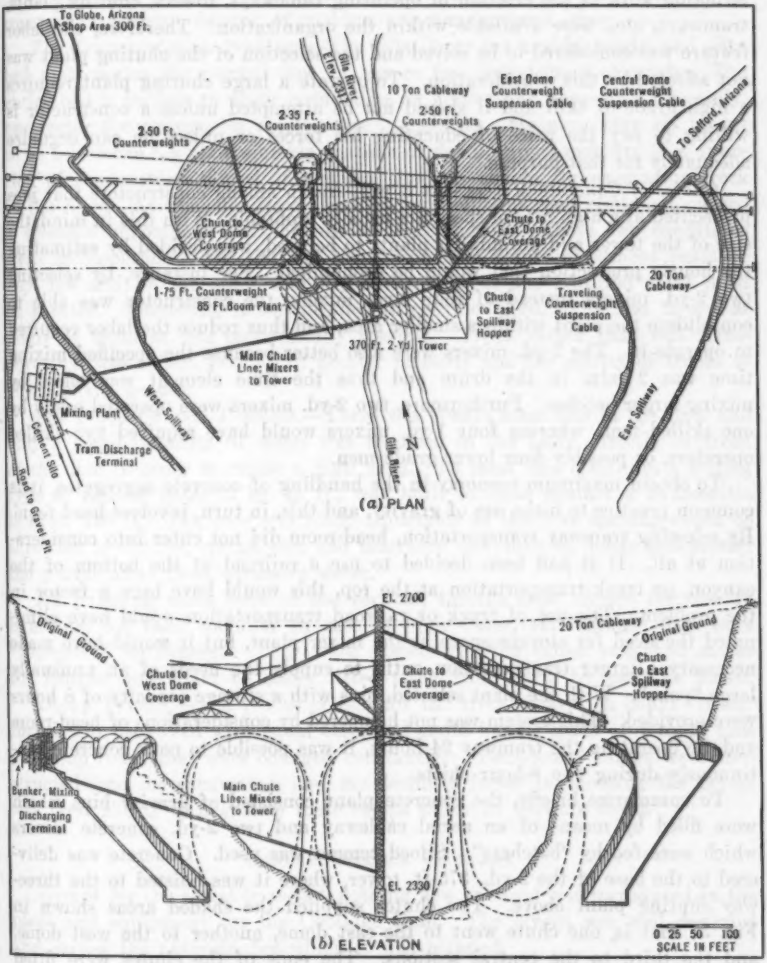

FIG. 3.—LAYOUT OF CONCRETE PLANT FOR COOLIDGE DAM.

*The Main Hoisting Tower.*—Despite the flood hazard, the main hoisting tower was located directly in the river bed. (See Fig. 2.) Side-hill towers would have involved re-hoisting the concrete and would also have entailed a

great first cost. In order to make the tower safe against high water, it was founded on a concrete pedestal which was sunk to bed-rock, and although it was not called upon to withstand a large flood, it probably would have been safe in the largest known run-off.

*Labor Problems.*—All the trained experts that were required for such construction work as the erection of operating cableways, towers, chuting plants, tramways, etc., were available within the organization. Therefore, the labor feature was considered to be solved and the selection of the chuting plant was not affected by this consideration. To operate a large chuting plant requires a high grade of skill and it should not be attempted unless a constructor is willing to pay the price of educating his forces or unless he can organize adequately for that purpose.

*Choice of Concrete Mixers.*—It is well-known among constructors that jobs prosecuted at a high rate of speed are usually profitable. With this in mind, the size of the tower and the mixing plants to be used, was decided by estimating the hourly production that would be economical. For instance, by selecting two 2-yd. mixers instead of four 1-yd. mixers, the constructor was able to consolidate the plant within a smaller area, and thus reduce the labor required to operate it. The 2-yd. mixers were also better because the specified mixing time was 2 min. in the drum and thus the time element was offset by mixing larger batches. Furthermore, two 2-yd. mixers were operated easily by one skilled man, whereas four 1-yd. mixers would have required two skilled operators, or possibly four lower grade men.

To obtain maximum economy in the handling of concrete aggregates, it is common practice to make use of gravity, and this, in turn, involves head-room. By selecting tramway transportation, head-room did not enter into consideration at all. If it had been decided to use a railroad at the bottom of the canyon, or truck transportation at the top, this would have been a factor in the problem. The use of truck or railroad transportation would have eliminated the need for storage space at the mixer plant, but it would have made necessary a larger transportation outfit to supply the needs of an unusually large "pour". With the plant selected, bins with a storage capacity of 8 hours were provided. This system was not hampered by considerations of head-room and, by operating the tramway 24 hours, it was possible to pour concrete continuously during two 8-hour shifts.

To summarize briefly, the concrete plant consisted of gravity bins which were filled by means of an aerial cableway and two 2-yd. concrete mixers which were fed by "batchers". Siloed cement was used. Concrete was delivered to the base of the 2-yd., 375-ft. tower, where it was hoisted to the three-way chuting plant above. The chutes supplied the shaded areas shown in Fig. 3; that is, one chute went to the east dome, another to the west dome, and the third to the central sections. The ends of the chutes were fitted with swinging counterbalances, as shown in Fig. 3. The 75-ft. machine at the center was used either by itself or in connection with two 35-ft. counterbalances that served the center dome. All swinging counterbalances were suspended from cables that stretched across the canyon.

The spandrel walls of the domes, the sidewalks, hand-rails, enrichments, etc., were poured by means of an automobile hopper car on a timber track. A total of 204 000 cu. yd. of concrete of all classes was used.

## The Excavation Plant

In planning for the excavation work, several selections were open to the constructor without danger of making any fundamental error.

*The Transportation Problem.*—The Gila River has a wide, sandy, and silty bed that carries the normal flow in one or two well-defined channels. The entire bed is subject to filthy inundation on almost any occasion. Certainly, one factor the constructor must secure is mobility. He must plan his layout so as to remove his plant quickly in time of flood. Since mobility is a function of size a steam shovel of medium size was chosen for excavation work in the river. At the same time, the high rock cliffs at each abutment offered a splendid opportunity for the use of large shovels. These two conditions were incompatible: On the one hand, the total plant investment must be kept low and, on the other, mobility and service at any required point must be assured. Therefore, it was decided to provide 1¼-yd. units and to use as many of them as was economically possible. Truck rather than rail transportation was chosen because of greater mobility and the ability of trucks to climb heavy grades.

*The Flood Control Problem.*—There was always some flow in the river and only a small quantity of water was required in the basin directly in front of the dam in order to create a high head. To meet this condition a sliding type of control gate, 12 by 32 ft., was built to close against a hydrostatic head of 150 ft. The gate was made adjustable so that the opening could be throttled to control, spread out, and minimize the effect of floods and protect the gravel plant from excessive water.

All pumping units were of the vertical, turbine type, chosen for ease in handling, for their mobility in case of high water, and because they were "fool-proof" in general. They were suspended from cables stretched across the canyon and could be easily lifted away from harm by gasoline hoists.

*Dump Trucks.*—The trucks chosen for the river excavation could "track" forward or backward with equal ease, and could handle loads of 7 to 10 tons on dump roads that were changed constantly. "Backdown" ramps were constructed into the excavation, and the deciding factor in choosing the trucks was their ability to negotiate these ramps safely by backing down.

## General Service Problems

Except for the aerial tramway, nothing new or novel was introduced in the plant and equipment for the Coolidge Dam. The layout was well designed and served the purposes for which it was planned.

*Crushing and Screening Plant.*—After selecting and locating the best type of mixing, chuting, and gravel transportation for the job, the next consideration was to erect a crushing and screening plant that would fulfill the requirements of the pouring schedule as planned.

The material in the gravel pit consisted of cobbles, boulders, silt, and mud, and it was, therefore, not possible to use it in its natural state as graded aggregate. It was necessary to furnish two digging units and a system of balanced transportation between these units and the primary crusher in order to overcome this feature.

The selection of equipment for the pit transportation plant was governed by ordinary economics and it was on this basis that a narrow-gauge track and "dinky" locomotives were chosen. The length of haul was the deciding factor in eliminating trucks. The digging units were chosen merely on the basis of judgment as to their adaptability to the particular kinds of ground to be excavated. A comparatively large shovel was used for the major digging operations and smaller ones for the secondary or "paging" work.

The gravel plant requires no further description than to state that it served all the purposes for which it was built.

*Cableways.*—The greatest care was taken in assembling the plant designed for "general services". Two inlet towers were located in the plane of the up-stream bed-rock contact. These towers received material during construction by means of a 10-ton cableway, which was also arranged to carry forms and reinforcing steel to the lower areas of the domes.

Most of the tonnage was delivered on the main 20-ton cableway (see Fig. 3), which was centered over the roadway of the dam. This material-handling service was augmented by several small trucks and one large truck which shuttled up and down the roadway between the camp, shops, and the bottom of the canyon.

*Shops and Service Pipe Lines.*—Two compressors fed a generous supply of air to the whole job. The power distribution was carefully planned and scrupulously maintained. The Electrical Department was completely equipped. An ice manufacturing plant was part of the layout and cold drinking water was supplied at various points on the job.

Air and water supply pipes were incorporated in all parts of the dam so that the forms could be readily cleaned and the concrete cured. The forms required were unique and the work entailed in erecting them was indeed a pioneering effort.

## The Construction Work

In brief, the construction of the dam required a combination of old ideas with newer methods. It may be considered as comprising three distinct classes of work: The buttresses, the domes, and the "top work", which was quite ornamental.

*The Buttresses.*—The construction of the buttresses presented no problems, except that it was complicated by the need of providing the engineers with a leveling control for the sloping "pours". This involved additional costs in shoring and in wires, but otherwise there was no difficulty.

*The Domes.*—These are enormous egg-shaped structures, rising in nearly vertical lines from the bed-rock to a plane about 50 ft. above. At this plane, the surface began to incline inward toward the vertex with the curvature gradually increasing until at the top the crown line was level.

The total horizontal distance from the up-stream bed-rock contact to the down-stream face at the top of the dam is 212 ft. and the total height about 245 ft. The walls were 20 ft. thick at bed-rock and tapered to 4 ft. at the top. The span of the domes increased from 94 ft. at bed-rock to 160 ft. at mid-height and then decreased gradually to 126 ft. at the top. The rises were 30 ft. at the bottom, 50 ft. at the center, and 24 ft. at the top.

For purposes of construction each dome was divided into three sections: The part from bed-rock to a plane 50 ft. above; that between Elevation 50 to a level near the top, where the spherical cap began to take shape; and, finally, the top.

To guide in setting the forms for the domes, survey points were set at each 4-ft. elevation. Therefore, the concrete would have to be set hard enough by 9:00 A. M. each day so that the surveyors could set new points promptly. Otherwise, the cycle would be broken and one working shift would be lost. This stipulation required that the yardage of concrete poured each day should be such that the plant could be used to full capacity and that the chuting system be made so flexible that the scattered areas could be easily reached.

It was found best to pour the buttresses and the quarter-spans of the adjacent domes in one piece. After such a section had been allowed to shrink 4 or 5 days, the central part of the dome was poured. This plan accomplished two things: It permitted pouring concrete in the buttress sections with very little moving of chutes, etc.; and it localized the sections of scattered pouring to the central arch parts of the domes. The flexibility built into the plant was made usable during the time of concentrated pouring so that a balanced yardage and form area were maintained.

Since the walls of the domes were of varying rates of curvature, flexible form panels, in assorted sizes, were used throughout. No difficulty was experienced until the over-hang of the intrados panels became greater than 35° from the vertical. To overcome this, reinforced steel tie-backs were set in each successive lift of concrete to hold the form in place. By means of these tie-backs the dome was poured nearly to the top and until the over-hang approached 54° from the vertical.

The caps were divided into two parts: That which lends itself to bridge treatment and another part, named "the wart", for which a new and novel treatment was devised.

The bridge, or roadway part, of the domes was supported on structural steel centering. The concrete was poured in balanced blocks in such a manner as to control deflections. Well-known and standard methods were used.

Steel U-bolts were cast into the bridge barrel to match a similar number cast into the last section poured in the dome where the degree of curvature was 54° from the vertical. In each dome, twenty-two bowstring trusses were suspended from the U-bolts, and the lagging to support the concrete for the top of the domes was constructed on these trusses. The loading on the trusses was distributed so that each section poured became self-supporting before a new load was applied. This method was found to be economical and provided for the necessary shrinkage in the concrete.

The pouring process on each "wart" took three weeks. No difficulty was encountered in their construction, but the design of the centering required all the ingenuity that could possibly be concentrated upon it. It was necessary not only that the superimposed loads on the trusses be carried safely and that the deflections be controlled, but also that over-stress be avoided in the parts of the incompleted domes used for supporting the trusses. This involved considerable "cut and try" designing.

The multiple dome was found to be a practical structure to build and a worthy contender for primacy in the high dam field.

# DISCUSSION

F. G. SWITZER,[11] Assoc. M. Am. Soc. C. E. (by letter).—In reading the interesting paper by Mr. Wiley, three points were noted with which the writer cannot agree. These may be summed up as follows:

*First.*—If a gravity dam is designed as a straight dam with the resultant line of pressure at the third point, then the same section built as an arched gravity dam will show no tension.

*Second.*—Arch action is always present in an arched gravity dam.

*Third.*—There can be no vertical stress in the concrete as a result of water, under pressure, in the voids.

The writer believes that the first and third of these points are contrary to fact and that in the second point the word, "always", should be replaced by the words, "not often."

As a matter of experience, the writer recalls an existing gravity dam, for which the first designs were those for a straight dam. The contours in the river bottom made it desirable to arch the dam in plan in order to utilize the best abutment sites and, at the same time, avoid a deep hole in the river bed. With the same section, computations showed that in the section reduced by convergence of the radii, tension would be present for some appreciable distance from the up-stream face. This design assumed full uplift pressure on the whole area at all elevations and with a maximum intensity equal to the full hydrostatic head. The section, therefore, was increased, and no reliance was placed upon possible arch action.

In order to examine somewhat more closely into the problem, the writer has considered the simple triangular section of a gravity dam, as shown in Fig. 4. The reduction in section due to convergence of the radii has been expressed by a fraction, $k$, which is the ratio of the base length of the dam, $b$, to the radius of curvature of the up-stream face, $R$. If the section has a length across the up-stream face of 1 ft., the toe of the section has then a length across the river of $(1 - k)$ ft. In order to simplify the work, the water level was taken at the top of the section, and no uplift pressures were assumed. The base length was determined from the consideration that the resultant pressure with a straight dam, $k = 0$, should intersect the base at the down-stream third point. Thus,

$$b = h\sqrt{\frac{w}{\rho}} \qquad (1)$$

in which, $w$ is the weight of water per cubic foot, and $\rho$ is the weight of the concrete per cubic foot. Computations were then made to determine the stress intensities at the up-stream face of the dam for any value of $k$ and, hence, for any radius of curvature. Without going into the details of the mechanics and algebra, the stress intensity, $S$, at the up-stream face, when considered as a vertical cantilever, can be found from Equation (2):

$$S = -\frac{\rho\, h\, k\, (2 - k)}{6 - 6\, k + k^2} \qquad (2)$$

[11] Cons. Engr. and Prof. of Hydr. Eng., School of Mech. Eng., Coll. of Eng., Cornell Univ., Ithaca, N. Y.

The negative sign denotes a stress which is tensile for any degree of convergence as expressed through values of $k$ between zero and 1. Let $\rho = 150$ and $h = 100$; then Equation (2) may be solved for $S$ by introducing successive values of $k$, as follows:

| $k$. | $S$, in pounds per square foot. | |
|---|---|---|
| 0 | 0 | tension |
| 0.1 | 526 | " |
| 0.2 | 1 116 | " |

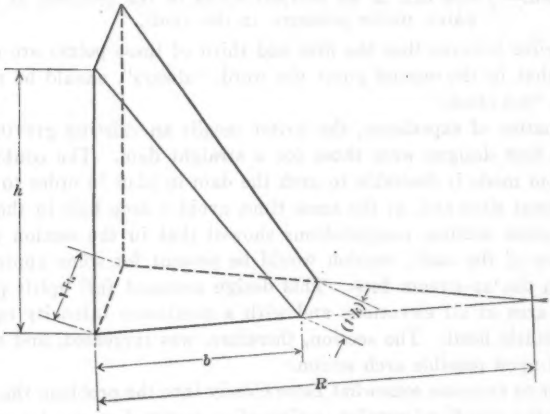

FIG. 4.—TRIANGULAR SECTION OF A GRAVITY DAM.

As for the presence of arch action, the writer has estimated the deflection of the section shown in Fig. 4 when considered as a vertical cantilever on unyielding foundations. Let $E$, for concrete, = 3 000 000 lb. per sq. in., $\rho = 150$ lb. per cu. ft., and $h = 100$ ft.; then, the top of the section deflects down stream about 0.032 in. With such a small deflection the convergence of the radii would not close up any contraction joints such as are used ordinarily between blocks of the dam, and, therefore, no arch action can develop. Arch action can be expected only when the contraction joints between blocks are carefully grouted at a time of low temperature or when the arch has a comparatively short radius of curvature. Since these conditions are not often found, it may be said that arch action in a curved gravity dam cannot be expected.

Finally, the writer would disagree with Mr. Wiley's reasoning which leads him to conclude that "there is no uplift in the body of a homogeneous mass of concrete". If a section of the dam above any given elevation be removed, in order to represent it as a "free body", according to the usual methods of mechanics, the plane of separation will cross voids as well as solid material. If the voids contained water under pressure, the severance of the structure requires that pressures equal to the water pressure be exerted upward where these voids existed. This is the uplift pressure. The opposite and downward

pressures are exerted upon the section of the structure below the line of separation and not on the upper section. If the voids contain water under pressure, then there will be uplift forces tending to create tensile stresses in the solid surrounding the voids and thus in the section of severance. Mr. Wiley's observation of the seepage of water from the body of the St. Francis Dam for weeks after the failure, must be considered as further conclusive evidence that water under pressure does permeate the voids in concrete dams.

FRED A. NOETZLI,[12] M. AM. SOC. C. E. (by letter).—In the design and construction of dams of ever-increasing height many new problems are encountered, some of which are of vital importance for the safety of such structures. If the law of similarity would hold in every respect, then, within proper limits, high dams built on an adequate foundation should be as safe as low ones.

Unfortunately, certain conditions have the tendency of making high dams relatively less safe than lower structures of the same type. Attention is called, in this connection, first, to the danger of buckling the face slabs of high earth or rock-fill dams due to a relatively larger settlement of the fill of the higher dams; second, to the complicated stress conditions and the tendency of tension cracks developing in the thick arches of high arch dams; and, third, to the tendency of cracks developing in the buttresses of high dams of the buttressed type, such as multiple-arch, Ambursen dams, etc. Only recently it was observed that shrinkage cracks have also occurred in the interior of high concrete gravity dams. While such interior cracks may not be serious in case of relatively low gravity dams in which the shear stresses are small, the stability of high gravity dams may be endangered if the cracks should extend in the direction of high shear stresses.

Large concrete dams of the gravity type, if built rapidly, develop high temperatures in the interior of the mass. Later, when the internal heat is being dissipated, the concrete shrinks and, being restrained along the rock foundation, is setting up tension stresses which may exceed the tensile strength of the concrete and produce cracks. In order to avoid such cracks, vertical contraction joints, usually about 50 ft. apart, are being provided in practically all concrete gravity dams. Not until after the failure of the St. Francis Dam was the definite proof available that similar cracking was likely to occur also in planes parallel to the axis.

In Fig. 5 are indicated some of the cracks which were observed in the remaining part of the St. Francis Dam after the failure. Water seeped out for several days after the failure, indicating that the cracks extended over considerable areas and were subjected to internal water pressure. A gravity dam, say, 250 ft. high, may be about 170 ft. thick at the base. There is no reason why the concrete should not shrink in an up-stream and down-stream direction the same as in the direction of the axis of the dam. Thus, in the 170-ft. thickness of the dam, the shrinkage of the concrete will probably produce cracks unless contraction joints are provided at suitable intervals. There is no other alternative unless new materials or construction methods are developed which will furnish concrete that does not shrink. As Mr. Henny pointed

[12] Cons. Hydr. Engr., Los Angeles, Calif.

out, "such cracks are likely to be approximately vertical and are thus often close to the direction of maximum shear."

Fortunately, the theory of the principal inclined stresses offers safe and adequate means for avoiding irregular internal shrinkage cracks by providing inclined contraction joints parallel to the direction of the principal stresses for maximum load. In these planes the shear is zero. Consequently, there is no tendency for a relative movement to take place in the parts of the dam on opposite sides of such joints. Contraction or expansion of the concrete may take place by opening or closing of the joints and with little or no effect on the load stresses in the dam.

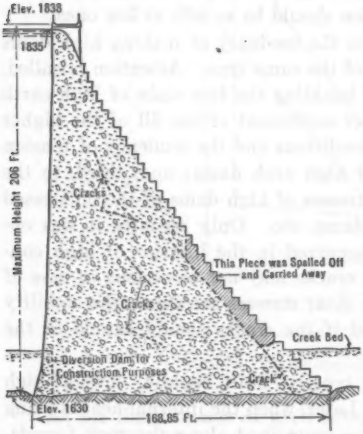

FIG. 5.—MAXIMUM SECTION, ST. FRANCIS DAM, SHOWING CRACKS.

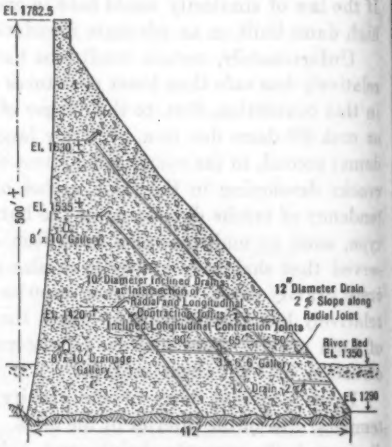

FIG. 6.—MAXIMUM SECTION, SAN GABRIEL DAM, SHOWING INCLINED JOINTS.

Fig. 6 shows the location of the three longitudinal joints in the cross-section of the San Gabriel Dam. The joints are offset in the sections on opposite sides of the vertical radial contraction joints. Interlocking keyways will prevent excessive movements of any portion relative to the adjoining portions so that the whole structure will act as a system of inclined columns, each of which is thoroughly interlocked with the adjoining columns. The inclined columns have a horizontal cross-section of approximately 50 by 60 ft. They may be built up individually for several lifts ahead of the adjoining columns so that at least a part of the shrinkage can take place before others are poured to the same elevation. Also, the individual pours may be interlocked with each other. In this case the inclined joints would have offsets of perhaps 6 to 12 in. each at intervals of, say, three or four lifts. If these offsets are troweled smoothly and painted with oil to prevent bond, a slight lateral movement corresponding to the shrinkage of the concrete could take place and thus the inclined joints made effective without material sacrifice of the strength of the structure.

In this connection attention is called to the San Mateo (concrete gravity) Dam built in 1887 and 1888 for the water supply system of San Francisco, Calif. This dam was constructed of blocks of concrete, 10 to 12 cu. yd. each, cast in place and thoroughly interlocked with each other. If the theory of the principal inclined stresses in gravity dams had been known at that time, and if the designer had arranged the up-stream and down-stream slopes of the individual blocks in continuous lines parallel to the direction of the principal stresses, this dam would be representative of the most advanced type of construction. Apparently, the designers and builders of the San Mateo Dam anticipated by sheer ingenuity or intuition a requirement in the construction of concrete gravity dams which only recently was substantiated by theoretical deductions. It can no longer be ignored without inviting possible disaster, especially in the case of high dams.

Similar conditions as to shrinkage cracks obtain in the buttresses of high multiple-arch and Ambursen dams. Cracks have been observed in the buttresses of many of these structures. Fortunately, in most cases they appear to have developed under load conditions, and their direction was guided by the laws of Nature to be approximately parallel to the principal stresses. Two engineering commissions recently investigated the Lake Hodges Dam in California. Both reported that the various inclined cracks, of which there is at least one in practically every buttress of the dam, did not render the dam unsafe. This conclusion seems to be substantiated by the fact that the Lake Hodges Dam, built in 1917, has since been filled several times. The buttresses contain practically no steel reinforcement; nor is any reinforcement apparently contemplated despite the presence of the cracks, some of which are nearly 0.1 in. wide and extend from the base of the buttresses forwardly inclined to practically the groin line of the arches.

The cracks in the Lake Hodges and other dams are evidently a good and sufficient proof of the feasibility, not to say, necessity, of providing large concrete dams, both of the buttressed and of the gravity type, with inclined contraction joints. The agreement of these "full-size tests" with the theory of the principal stresses is quite satisfactory and is further subject to verification by constructing in the ordinary way the force and string polygons for water load and weight of the individual parts of the dams separated by the joints. This was done in the designs of the Coolidge (multiple-dome) Dam, completed in 1929 for the U. S. Department of the Interior, Indian Service, on the Gila River, in Arizona, and for the San Gabriel Dam.

Mr. Wiley's statement that, in his opinion, "the higher dams of the future will be of a solid masonry gravity type," is somewhat startling. As a matter of fact the two highest dams built so far, namely, the Diablo Dam on the Skagit River in Washington, 385 ft. high, and the Pacoima Dam in California, 372 ft. high, are of the single arch type. There is under construction in France an arch dam which, when completed, will be 440 ft. high. This dam is located in the extremely narrow canyon of the Drac River in the French Alps and is only 55 ft. thick at the base.

The Owyhee Dam, 405 ft. high, mentioned by Mr. Wiley as being of the arched gravity type, was designed and is being built as an arch dam.[13] Further-

[13] *Western Construction News*, January 10, 1929, p. 9.

more, studies are being made to determine whether the proposed Boulder Canyon Dam, 680 ft. high, can not be designed to act as an arch, at least in the upper portions, thereby decreasing the enormous quantity of concrete required for a pure gravity dam while at the same time increasing its safety factor against overturning and sliding. Thus, it is seen that the highest dams so far built or under construction are not of the gravity but of the single arch type.

Dams of the buttressed type, after cautious beginnings some time about 1910, have already been built to a height of 250 ft. There is no reason why dams of this type should not be built with perfect safety to still greater heights. Undoubtedly, this will be done sooner or later.

A gravity dam has a true factor of safety of less than two. This is less than for any other type of engineering structure. Furthermore, such a dam is subject to uplift pressure and to internal tension stresses of unknown, but certainly of large size, sometimes resulting in cracks such as have been observed in the interior of a number of dams of this type. While these cracks appear to be of small consequence in case of relatively low dams, because the shear stresses are small, they are of increasing importance for high dams especially if, as Mr. Henny pointed out, the cracks should occur in planes of high shears.

It is generally believed that the design of a gravity dam is a simple matter and permits of an easy determination of the stresses. Recent investigations have shown, however, that a scientific design of a high gravity dam is a fairly difficult problem; at the same time it involves relatively large uncertainties, especially as regards the applicability of the law of the trapezoid for the stresses in thick dams, uplift pressure, internal temperature, and shrinkage stresses, etc. While some of the same difficulties are encountered in the design of high buttressed dams, the tension stresses in the buttresses may be taken care of by steel reinforcement; a similar procedure is not economically feasible in the case of gravity dams.

From these considerations and in view of the recent construction of numerous high dams of "less than gravity" section, does it not appear that there are strong tendencies toward building future dams of other than the concrete gravity type?

Edward Godfrey,[14] M. Am. Soc. C. E. (by letter).—The entire subject of dams, in the writer's judgment, needs to be thoroughly and freely discussed. The design of dams will never be on a sound footing until the strenuous objections to standard methods of a small, very small, but growing minority of engineers are met and clarified.

The writer is one of those who hold that standard design is woefully inadequate and has been responsible for practically all the large number of failures of masonry dams. The one great and serious fault can be simply stated: It is neglect of under-pressure. That it is in truth standard to ignore under-pressure in the design of dams can be proved in many ways. In the first place very few books on the design of dams mention or give any prominence to under-pressure. Many of those that do mention it, treat it as if it were

[14] Structural Engr., Pittsburgh, Pa.

merely a refinement—something for the designer's judgment. Some writers even refer to it as a bugaboo.

That it is standard to neglect under-pressure in designing dams is also shown by the statement of Mr. Wiley that in many, if not most, straight gravity dams, no allowance has been made for uplift.

There has scarcely ever been a failure of a masonry or concrete gravity dam where the entire action of the dam cannot be fully explained by supposing that water under pressure worked its way under the dam or into a horizontal joint and lifted the dam, allowing it to float away or to be overturned; and there has never been a dam lifted and pushed down stream where the mass and base width were sufficient to hold it in place against assumed up-stream and under-pressure. Unless the truth of these statements can be denied, they stand as an unanswerable argument for unconditional provision for under-pressure and against standard methods that ignore under-pressure under any condition whatever. It is no answer to state a contrary opinion. The only refutation of these statements of any value is the citing of one or more dams the failure of which can not be explained by under-pressure, or of one which floated off, as did the St. Francis Dam, although the base width was 85% of the height instead of 65% as was that dam.

In reading Mr. Wiley's paper one would be led to believe that under-pressure is of little consequence and internal pressure, even in porous concrete, is non-existent. From Mr. Henny's paper one would be led to believe that under-pressure is easily averted or avoided.

Mr. Wiley states that:

"The absence of stress due to uplift in the body of the concrete appears from the consideration that the water can act only in the voids. The pressure in a void in the concrete is in all directions, and considering only the vertical pressures in a single void, it might appear that a tensile stress in the concrete would result; but considering that the upward and downward forces in each void are opposed and cancelled by equal downward and upward forces in the voids immediately above and below, it is readily seen that the summation of the vertical forces in the voids is zero, and that no vertical stress in the concrete can result from water pressure in the voids. This has also been shown by the application of enormous pressures to a liquid without effect upon the concrete or other porous substance immersed in it."

This is a new line of reasoning which, if valid, calls for a recasting of the theory of pressures. It would mean that a liquid could be carried slowly through a spongy mass under high pressure without exerting tension on the pipe. It is easy to see that a spongy mass embedded in a fluid under pressure is not subject to tension in its own fibers by reason of the pressure; but, at the same time, if there is enormous pressure there is enormous tension somewhere that exactly balances it. The tension is not in the sponge but in the vessel containing and restraining the fluid. Suppose that the sponge itself is the vessel; suppose the outer skin of a sponge were elastic and impervious and that the sponge were filled with water under pressure. Every fiber of that sponge would be subject to tension. It requires no test to prove this. If there were a spongy layer in the concrete of a dam, and water entered that and was prevented from escaping on the down-stream face (and the caretaker would see to it that the joint would be sealed up), there would certainly be tension

in the concrete, a tension exactly equal to the pressure. This is directly contrary to Mr. Wiley's statement of the case, but it is the law of fluid pressure and of mechanics.

Furthermore, this is just what happened in a remarkable case of the flotation of a pier[15] which split at a construction joint in the concrete. The upper part, weighing about 1 000 tons, was lifted by pressure of water that entered this joint in the seemingly solid concrete. The great weight of the pier and the friction against the coffer-dam, as well as what tensile strength the concrete possessed, were not sufficient to overcome the water pressure in the pores of this concrete, which, by Mr. Wiley's statement of the case, should be balanced and equal to zero.

The several means used to inhibit under-pressure in dams are: Cut-off walls, grouting fissures, and under-drainage.

Consider, first, cut-off walls. If water under-pressure has an outlet, the pressure will be reduced. If it has no outlet, the pressure will tend to reach that of the head, or the vertical distance to the free water surface. The distance through which the water and the pressure travel has influence only as affecting the time necessary to accumulate the full head. The value of cut-off walls is, therefore, simply to delay the accumulation of pressure. They do not prevent it, unless the water has a more or less free outlet.

The fact is that several dams have failed, that had one or more cut-off walls, but were too light for stability. Another fact is that pressures have been measured and found to be very considerable down stream from cut-off walls.[16]

If cut-off walls prevented pressure of water under a dam, there would never be a failure of a dam having a cut-off wall; because if the water were not in the foundation exerting pressure, even the standard reason for dam failure, according to all reports, would have no basis in fact.

Grouting fissures in a foundation is considered to be the one unfailing inhibitive against under-pressure. The basic idea behind this is that water can enter only where there is an actual fissure—an opening. A crack would not be classed as a rock fissure; and, furthermore, it would be quite impossible to grout up a crack. In fact, there are fissures that it would be practically impossible to fill with grout, even under pressure. Experience in grouting thin cracks has proved that the water of the grout will penetrate the crack and leave the cement. It stands to reason that solid cement or colloidal cement will not penetrate thin crevices where water may freely go. It is a well-known fact of hydraulics that water will exert its full pressure in the finest crevice.

Furthermore, it is not always possible to find all the rock seams. Some of these may be in a horizontal direction just beneath the base of a dam, and drilling would not disclose their presence. The cracks most difficult to grout are the horizontal ones, and these are the greatest menace to the stability of the dam.

In view of the facts just stated the stability of a dam that is dependent on the inhibiting of under-pressure because all rock seams are supposed to be fully grouted and impervious, is seen to be precarious.

[15] *Engineering News-Record*, March 13, 1904.

[16] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), pp. 1532, 1537, and 1543.

The third method of avoiding under-pressure is drainage. This requires an expensive system of piping. There is no way to determine the effectiveness of the system. It is likely to silt up and be made useless. In cold climates the outlet is liable to freeze. The failure of more than one dam that occurred in cold weather was doubtless due to freezing of the weep-holes.

Water, working toward the drainage pipes under a dam, must of necessity exert pressure. This pressure will act against the base of the dam; hence, the only relief will be in the immediate neighborhood of the drainage pipes. Under-drainage is then, also, seen to be of precarious and unknown value.

Still another method used to prevent under-pressure is the driving of sheet-piling. This, too, has been found to be ineffectual in stopping pressure.[17] This method could be used only where the soil admits of driving sheet-piles, and such soil, not being solid and strong rock, would be classed by some as unsuitable for the foundation of a dam.

The evidence that under-pressure exists in many dams and may have a large value in any dam is overwhelming.[18] The possible pressure under the St. Francis Dam, for example, was hundreds of millions of pounds, which is a gigantic force to provide for, and a still more gigantic force to ignore.

It is pertinent to look into the arguments, the tests, and the ideas that influence some engineers to ignore under-pressure in the design of dams. The idea persists that, unless there is tail-water, there can be no flotation. This is born of the notion that, unless an object is immersed, it cannot float. Designers lose sight of the fact that it is in no sense the influence of water pressure on the side of an object that makes it float; it is solely the pressure of the water beneath it.

It is universally conceded that, where there is tail-water, there is flotation, or buoyancy equivalent to the loss of weight for the depth of that tail-water. It certainly is not pressure of water on the sides of the dam that is responsible for this buoyancy; it is, of necessity, pressure of the water beneath, and that water must work its way under the dam. There is greater facility for water and pressure to enter from the up-stream side than from the down-stream side because of the greater head.

One argument for adhering to the standard method of designing dams and ignoring under-pressure is that there are dams standing which are not proportioned for any under-pressure. The St. Francis Dam was in that class just before it failed. A large number of other dams that have failed stood in that class for as long as 40 and 50 years.[19] Some of these dams failed under a head of water lower than they had resisted in previous years.

A fact lost sight of is that it requires some time for water to penetrate and still more time for the pressure to build up. A high-water period may not last long enough for a destructive pressure to accumulate, and the false notion is fostered that the dam is stable. In other structures loads have an immediate effect, and a test load is conclusive.

[17] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), pp. 1537 and 1556.

[18] *Loc. cit.*, pp. 1317 and 1527.

[19] *Engineering News*, April 9 and June 4, 1903; *Engineering Record*, April 27, 1912, p. 476.

Furthermore, time has a controlling influence because the accumulation of silt may serve to clog the outlet where water escapes below a dam and thus allow the building up of pressure. The stopping of leaks below a dam, either by Nature or by the caretaker, is equivalent to driving a gigantic wedge beneath it.

The statement is sometimes made that water beneath and in a dam is present because of capillarity and that the dam is, therefore, not subject to pressure. It is well known that water leaks out below dams. If that is an exhibition of capillarity, there is a chance for some one to invent perpetual motion. Just suck up a lot of water to a high level by a system of sponges, and let it run away as free water to run turbines, and the question of power is solved.

It is argued that pressure on the bottom of an object (in sand, for example) can be only a fraction of the computed head because there is contact on part of the surface of a grain of sand where there could be no pressure. This argument ignores the fact that the next layer of sand grains will press against the one in contact and make up fully for any such contact.

Experiments have been made tending to show greatly reduced pressure by reason of contact in sand grains.[20] Strangely enough, this is attributed by some to voids in the sand. Such voids are a volumetric property; pressure is purely a superficial matter. There could be no relation between sand voids and pressure of water in those voids because pressure is totally independent of volume.

Tests of such properties made on only a few inches of water are unreliable, as many uncertain and unknown elements enter. For example, unless the small cylinders are plunged deeply into the sand, practically full head is shown by their rising out. In the deep position, however, the starting friction (augmented by pressure on top of the sand), air bubbles in the sand, and the time element for the accumulation of pressure, combine to show an apparent upward pressure of only a fraction of the actual head.

In the well-known process of jetting piles in sand one has only to apply the water at the bottom of the pile, and it will sink in. Let the sand settle around the pile, and it is very difficult to drive or to pull it.

Air bubbles and cohesion in the sand due to the presence of clay would have a measurable influence in tests where only a few inches of head is considered. A few inches of sand could be held together by these means and the lifting action would account for part of the head.

Tests of high heads have shown, in dams and dry docks and in laboratory experiments, that under-pressure is practically 100% after sufficient time has elapsed for the pressure to build up.[21] In the face of these actual practical tests it is foolish to set up others on miniature models, with all the attendant uncertainties already mentioned, and to design dams on the basis of these small tests, setting aside the proofs of large-sized models and actual experience of failures.

[20] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1334.
[21] *Loc. cit.*, pp. 1330, 1331, 1333, and 1354.

Pressure in so-called impervious soil, while it may take more time to build up, cannot be assumed to be less than in sand. The soil above and below the tunnels in New York, being silt and clay, would seem to be classed as impervious; but this soil shows most remarkable response to fluid pressure. It is observed that the tubes sink and rise as the tide rises and ebbs. This demonstrates, not only that this "impervious" soil transmits and exerts pressure, but the further fact that it requires some time for this pressure to travel through the mass; for if the pressure were transmitted at once, there would be no difference between the differential of top and bottom pressures at high and low tides, and thus there would be no movement of the tubes.

The writer believes that in practically every dam that has failed the reported reason has been "foundation failure"; but in no case, so far as he has been able to learn, have the successive steps of that foundation failure been described or analyzed. Excessive soil pressure due to weight cannot account for it, because that would merely make the dam sink. The earth cannot wash away unless there is a crevice through which water can flow; and, so long as the dam is in contact with the soil, there can be no such crevice.

The term, blow-out, is sometimes used to describe the failure. A blow-out of soil connotes high pressure, and high pressure under a dam is something non-existent, according to those who make this explanation and fail to see that that high pressure would lift and float a dam not proportioned to resist it long before it would issue in a blow-out.

It would be impossible for rock, no matter how poor a quality, to issue in a blow-out. Only fluid or semi-fluid soil could be forced out from beneath the base of a dam.

It is the foregoing arguments against the neglect of under-pressure that make it incumbent on the Engineering Profession to do one of two things, namely, either to answer these arguments in a free and open discussion or to revise their standards of designing dams.

Mr. Wiley mentions the economic advantage of arch action in dams. Reading his remarks, one cannot fail to gather the idea that merely curving the dam in plan makes an arch of it. Nothing is said of the abutment or the need of an abutment. A curved dam is merely a curved dam; it is not an arch, unless it has adequate abutments at the ends of the curves. Dams like the St. Francis Dam are not arches, for they taper down to practically nothing at the very place where gigantic abutments should be located. If suitable abutments for such long dams, not in rock gorges, were included in the design, the seeming economy would vanish. At least, two long, curved dams have failed because their designers considered them as arches, but supplied no abutments.[22] This is another of the major errors in standard dam design.

B. F. JAKOBSEN,[23] M. AM. SOC. C. E. (by letter).—In his paper Mr. Wiley defines arched gravity dams, as follows:

"In the case of the arched gravity dam there is a massive section capable of carrying the full load by its weight alone and, in addition, there is the resistance of the massive horizontal arch."

[22] *Engineering News-Record*, October 13, 1926, p. 616.

[23] Cons. Engr., Los Angeles, Calif.

This is, in the writer's opinion, a correct definition and the only logical one. It is quite important that engineers should agree on a definition for gravity dams.

Elsewhere in his paper Mr. Wiley lists the Exchequer Dam as an arched gravity type, although the writer has shown that this dam has a tension of about 40 lb. per sq. in. at the up-stream face, when concrete is assumed to weigh 152 lb. per cu. ft.[24] This dam, therefore, does not conform to Mr. Wiley's definition, since it will not stand by its weight alone, even when no uplift is assumed, and it should not be classed as a gravity dam. In discussing this subject further, Mr. Wiley states:

"In all these and in many other dams of similar design, the convergency of the radii is assumed to be offset by arch action and the uplift reduced, by pressure grouting and drainage, to an amount which can be taken care of by arch action."

This statement does not conform to the author's definition. That an arched gravity dam must be treated as such and not as a straight dam, the writer has argued fully in a recent paper,[25] and he notes with satisfaction that Mr. Henny agrees with this and also includes uplift. The writer can only insist that the factor of safety of a dam should be a calculable quantity and not something which is assumed; and he cannot agree to assume that arch action in general has certain beneficial qualities, unless these can be shown to exist and their magnitude calculated. Likewise, the writer is unwilling to assume that arch action in unknown amount can offset an unknown amount of uplift, as is done by Mr. Wiley. To assume no uplift is to make the least conservative assumption possible and is not, in the writer's opinion, good engineering.

In discussing the arch section *vs.* the straight section, Mr. Wiley states:

"* * * if there are no open joints extending entirely through it, the slightest deflection of the dam as a gravity cantilever will cause an equal deflection in the horizontal arch and a division of the load in some proportion between the cantilever and the arch."

This assumption overlooks the fact that before shrinkage cracks appear, the concrete must be in tension; and, in that case, a deflection of the dam as a gravity cantilever will not cause the arch to take any part of the load. Before this can happen, the cantilever must be deflected sufficiently for the arch to be relieved of all tension produced by shrinkage of the concrete. It is this fact and others, which makes the calculation of the division of load between the cantilevers and the arches so problematical. It has convinced the writer and other engineers that gravity dams should be designed as such, irrespective of arch action, and that arch dams should be designed as such, irrespective of any possible cantilever action.[26] This opinion was evidently shared by Mr. Wiley himself, who a few years ago wrote:[27]

[24] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), pp. 772 and 835; see, also, Mr. Wiley's discussion on p. 821.

[25] *Loc. cit.*, p. 766.

[26] "Stresses in Thick Arches of Dams," by B. F. Jakobsen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 516, Article XXI; see, also, the writer's remarks; *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 844.

[27] *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 116.

"It appears to the writer that in designing any arched dam of either full gravity, or reduced gravity, section all stresses should be considered as transmitted in either vertical or horizontal planes."

That arched gravity dams develop shrinkage cracks and leakage was brought out by the writer in discussing the Mulholland Dam[28] and E. W. Kramer, M. Am. Soc. C. E., recently stated:[29] "Some further reference to the Mulholland Dam will be made to prove that the contraction of concrete in a dam is real and not theoretical."

That dams not provided with contraction joints must develop cracks has been stated by Mr. Wiley,[27] as follows:

"Nearly all high dams * * * are of necessity provided with construction joints if not contraction joints. If they are not so provided, they are sure to crack into sections at points which cannot be determined in advance. It is impossible to build, or at least to maintain, a large dam as a monolith."

The writer agrees with this statement, but does not see how Mr. Wiley's Conclusion No. 3 can be made to agree with it.

In discussing uplift inside the dams Mr. Wiley appears to confuse external forces with internal stresses, and his attempt to reason uplift out of court does not carry conviction. Before it can be safely disregarded, it must be shown not only that it does not occur, but that it cannot occur in actual practice.

Under the heading, "Pressure Grouting of Contraction Joints," Mr. Wiley gives it as his opinion, that such grouting would be of no appreciable value and that the joints would only be filled for a distance of about 15 to 20 ft. from the faces of the dam. In making this statement, he probably overlooked the elastic property of concrete, since he mentions filling the contraction joints. Some years ago, L. R. Jorgensen, M. Am. Soc. C. E., suggested[30] pressure grouting of the contraction joints of single arch dams with a view of compensating for shrinkage. By pressure grouting Mr. Jorgensen has been able to force the crest of a dam up stream, thereby demonstrating that the process was something more than merely filling the contraction joints. Fredrik Vogt, Assoc. M. Am. Soc. C. E., has applied for a patent on a multiple grouting system,[31] which aims to equalize the arch stresses, as far as possible.

Mr. Wiley's Conclusion No. 4 reads:

"If the contraction joints should open so as to prevent arch action, water entering the joints would reduce, by its back pressure, the effective head on the dam and compensate for the loss of arch action."

The writer does not understand this. As already stated, there may be no crack, but there may be tension, which would prevent arch action just as effectively as an actual crack. Possibly Mr. Wiley could work out an example in figures to illustrate and amplify his remarks.

Mr. Henny refers to the experience with the Crystal Springs Dam in the San Francisco earthquake and concludes that very severe earthquake shocks

may be borne safely by straight gravity dams. Professor Ransome refers to the same dam, and neither calls attention to the pertinent fact that the dam referred to (the San Mateo Dam) has a section about twice that of the ordinary so-called gravity dam, which is designed with no allowance for uplift and is barely stable when the reservoir is full. The San Mateo Dam is 146 ft. high, 41 ft. wide at the crest, and 176 ft. at the base. The St. Francis Dam, which was a typical so-called gravity dam, had a crest width of 16 ft., and, for a height of 146 ft., its base width was 101 ft.[32] The San Mateo Dam has a stability of approximately four times that of most so-called gravity dams. It is evident that any experience with the San Mateo Dam does not apply to gravity dams in general.

Mr. Henny calls attention to the fact that concrete shrinks in setting, largely due to the cooling action. Transversal shrinkage cracks in dams have been often observed, and Mr. Henny suggests the possibility of shrinkage cracks inside the dam, the planes of which would be more or less parallel to the up-stream and down-stream faces. Such cracks have appeared in a number of multiple-arch buttresses, and the possibility of similar cracks in gravity dams was first suggested to the writer by Dr. Vogt, in 1927, after he had inspected some high gravity dams. Some such cracks were found in a gallery of the Elephant Butte Dam, but these extended only a few inches from the surface. They were, moreover, very irregular, thus suggesting that they were only surface cracks. The writer thinks there is much less danger of such cracks developing in a gravity dam than in multiple-arch buttresses, but Dr. Vogt's suggestion merits careful consideration. So far as the writer knows, no such cracks have been found in gravity dams, and Mr. Henny does not mention any examples from his own experience. He refers to some contraction joints parallel to the axis of the dam as being provided in the design of the San Gabriel Dam. It is the writer's understanding that these joints have been abandoned, and in his opinion such an innovation should not be tried in the highest dam thus far attempted.

The one serious objection to proceeding with higher dams of the gravity type has not been mentioned by either Mr. Wiley or Mr. Henny. This is the question as to the accuracy of the fundamental assumption that the vertical stress distribution across a horizontal plane is linear. There is neither experimental nor theoretical verification of this assumption, which has been borrowed, somewhat uncritically, from the theory of bending of long beams. Whatever evidence of a theoretical and experimental nature there is, it is against the usual assumption. The tests of Messrs. Ottley and Brightmore in 1908, referred to by Mr. Henny, as well as the tests by Messrs. Wilson and Gore, clearly indicate a non-linear stress distribution, as do also recent tests made by Dr. Vogt. Application of the principle of least work to this problem also gives a curved stress distribution and shows tension in the up-stream face, in cases where the ordinary theory gives compression. Even a small amount of tension in the up-stream face is extremely dangerous, in that there is a tendency for this to extend itself, especially if aided by uplift.

[32] *Proceedings*, Am. Soc. C. E., January, 1929, Papers and Discussions, p. 223.

The writer concludes, therefore, that tests to determine the actual stress distribution in gravity dams are badly needed before the height limit is materially increased.

As to whether a high arch dam is to be preferred to an arched gravity dam of equal height, that, in the writer's opinion, depends upon the site and its general characteristics, and no general rule can be laid down. If there is any question about the foundation being sufficient for a high arch dam, the writer would not consider a gravity dam either, unless it was of extraordinary dimensions, such as the San Mateo Dam. As between a properly designed arch dam and a gravity dam designed as outlined by Mr. Wiley, that is, on the assumption that the convergence of the radii and the influence of uplift are offset by arch action, the writer would invariably prefer the arch dam.

Professor Ransome presents the viewpoint of the geologist. Any careful engineer will always insist upon obtaining competent geological advice and will then make his own investigations and tests and draw his own conclusions, bearing in mind that the responsibility is his. Geology is, relatively speaking, a general science. It is often limited to reasoning on possibilities and probabilities and from effect to cause, which is always a precarious and dangerous proceeding, unless its limitations are well understood. It is the geologist's office to inform the engineer of the general nature of the surroundings, the character of the rock, the probability of earthquake movements and shocks, their probable intensity and direction, etc. It is not the office of the geologist to express himself regarding the stability of a dam. That is a matter to be decided by the engineer after carefully made calculations based upon such experience as he may have at his disposal.

The geologist reporting on dam sites needs some general understanding of what kind of information the engineer wants, and the engineer should bear in mind that geology is general rather than specific. In this way the best co-operation will result between engineers and geologists, and such co-operation is absolutely necessary in order to avoid costly and fatal mistakes.

ALLEN HAZEN,[32] M. AM. SOC. C. E. (by letter).—At a time when more and higher dams are being built and when examples of dams that have failed or partly failed, are accumulating at an unprecedented rate, Mr. Henny's words of caution are most timely. Dams certainly do not follow the law of models, and proportions that stand at one height cannot be taken as an argument for safety in a much higher dam of the same proportions.

In presenting the subject of safety in dam construction to the World's Engineering Congress in Tokyo, Japan, in November, 1929, the writer pointed out that the function of a dam is to absorb the water pressure upon it and carry it to the sides and bottom of the valley and to distribute that pressure, together with that resulting from the weight of the dam, over and through enough of the natural material in place so as not to stress any part of it unduly. The pressures that must be absorbed and transmitted are among the largest that engineering structures of any kind are called upon to carry, extending to hundreds of thousands and even to millions of tons.

[32] Cons. Engr. (Hazen, Everett & Pirnie), New York, N. Y. Mr. Hazen died on July 26, 1930.

A strong, light dam may concentrate the pressure on the sides and bottom of the valley beyond the ability of the foundation material to withstand; and it avails nothing to have the dam strong enough if the natural material is not fully competent to hold the resulting stresses.

Mr. Henny does not mention the thought that has been held by some engineers for many years, namely, that a gravity masonry dam of dimensions such that the line of thrust comes at the limit of the middle third, in reality, does not have any proper factor of safety. Many such dams have been built and some of them have failed. It may be true that those that stand depend upon tensile strength in parts of the masonry and resistance to torsion and shear and similar secondary means of resistance for any factor of safety that they may have. Furthermore, it may be that the weight of such a dam is in almost exact balance with the water pressure and is stressed by that water pressure so that if secondary sources of strength are excluded it is stressed almost to the point of rupture.

Nearly all dams in the last analysis are held by friction. It may be friction of masonry on masonry, or masonry on rock, or rock on rock. The friction in all these cases and at all possible lines of slipping must be sufficient to take up the thrust of the water pressure.

There is reason to think that the friction of masonry on some rocks and of the rocks on themselves may be much less than has been commonly supposed—and much less than would be prudently assumed for granite and other hard rocks. There is also reason to think that the frictional resistance of some rocks does not increase in proportion to pressure as is usually assumed.

The sliding of great dams presents many interesting problems which seem to have much in common with such phenomena as the slides at the Panama Canal and other great landslides. There is much uncertainty as to many factors, and increased weight is, in general, the surest road to safety.

H. DE B. PARSONS,[24] M. AM. SOC. C. E. (by letter).—While the four papers, forming the Symposium, contain many valuable suggestions, there are some statements that the writer would like to discuss.

Mr. Wiley lays stress on "the necessity of hard and durable rock foundations" as a rigid limiting condition for masonry dams. Such a condition certainly is much to be desired, but is not always available. A safe masonry dam can be built on "poorer" rock to heights that could be considered high, if given a suitable section. For a thin arch dam, however, "good" rock is essential. It is questionable whether the horizontal arch action in an arched gravity dam, having the same cross-section as a straight gravity dam, would offset the reduction in gravity action due to the convergency of the radii. The amount of horizontal arch action obtained would depend on the length of the radius and on the height of the dam. The water pressure on a gravity dam is considered as carried by the cantilever action. Assuming the base rigidly fixed to the rock, the deformation of the masonry would be a function of the height. If the same dam were arched, the radius would have to be

[24] Prof. Emeritus, Rensselaer Polytechnic Inst.; Cons. Engr., New York, N. Y.

relatively short or the dam very high before the compression of the masonry, due to deformation, would cause an horizontal arch thrust that would be truly effective at the buttress ends. With a long radius, the deformation probably would be taken up by closing vertical contraction joints.

A reading of Mr. Wiley's paper leaves the impression that hydrostatic uplift is not an important element, especially under arched gravity dams. All reported observations under actual dams show the presence of uplift.[35] Uplift would seem to be an actual force, like gravity or reservoir water pressure. Recorded observations show that grouting under the up-stream edge of the base does not eliminate uplift, and the assumption that it will is not founded on fact. It may lessen the uplift, but the reduction is questionable. When grouting is practiced, it would seem safer to use low pressures. The high pressures (say, from 80 to 150 lb. per sq. in.) often used may open the seams in a rock foundation and thereby cause increased uplift.

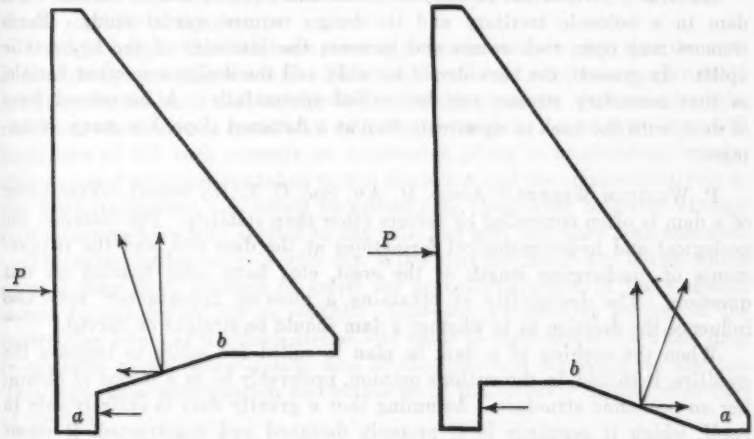

FIG. 7.—EFFECT OF FORM OF BASE OF DAM ON SLIDING.

The conclusion may be true that "there is no uplift * * * in foundation rock which is free from seams, nor in a perfect connection between the dam and the bed-rock", but such perfect conditions are not found at the sites for high dams. It would not be safe to design an important dam or a high one under such assumptions. Uplift under the base of a dam is a natural force, and the shape or material of a structure does not change this law of Nature. If it exists under a straight structure, it would also exist under an arched one.

In Mr. Henny's paper hydrostatic uplift under dams is given recognition. The writer believes that it cannot be entirely "prevented" although it may be reduced. The form of the dam base may have an effect on sliding due to

[35] "Hydrostatic Uplift Under Masonry Dams," by H. de B. Parsons, M. Am. Soc. C. E., *Paper No. 313*, World Eng. Congress, Tokyo, Japan, November, 1929.

hydrostatic pressure. In Fig. 7, two sections for gravity dams are shown that differ in their base planes. Hydrostatic head acts normally to the surface. With Section *X*, the head acting against the cut-off, *a*, and the horizontal component acting on the slope between *a* and *b*, would be opposed to the reservoir pressure, *P*, and, therefore, would diminish the tendency to slide. With Section *Y*, the horizontal component of the hydrostatic head acting on the slope between *a* and *b*, would be in harmony with the reservoir pressure, *P*, and would thereby increase the tendency to slide.

Deflection of the masonry, acting as a cantilever, affects the stresses at the up-stream edge of the base. At this edge, uplift is usually at a maximum. Therefore, the stress across the base joint, between the rock and the masonry (or concrete), may be changed from compression to tension, and the intimate contact between masonry and rock may be weakened or the rigid connection lost.

As clearly pointed out in Professor Ransome's paper, the foundation for a dam in a volcanic territory and its design require special study. Earth tremors may open rock seams and increase the intensity of the hydrostatic uplift. In general, the base should be wide, and the design somewhat flexible, so that secondary stresses can be carried successfully. A buttressed form of dam, with the back or up-stream face at a flattened slope, has many advantages.

P. Wilhelm Werner,[36] Assoc. M. Am. Soc. C. E. (by letter).—The layout of a dam is often controlled by factors other than stability. For instance, the geological and hydro-geological formations at the dam site, and the requirements of discharging length of the crest, etc., have some bearing on this question. The desirability of obtaining a pleasing appearance[37] may also influence the decision as to whether a dam should be straight or curved.

When the arching of a dam in plan is called for solely to improve the stability, it should, in the writer's opinion, preferably be as a means of obtaining an economic structure. Assuming that a gravity dam is entirely safe in itself, which it certainly is if properly designed and constructed, it seems rather unnecessary, except in special important cases, to impose upon this dam an additional condition involving expenses with a view to increasing the factor of safety. This is especially true, if the conditions are such as to give the arch action only a more or less hypothetical value, until the cantilever has been broken.

Obviously, there is a continuous transition between the pure arch and the gravity section. The question as to whether, under certain conditions, a division of the load takes place between the arch and the cantilever need not be discussed. The writer believes that this is often more or less a matter of computation, and lately it has been so treated in many instances.[38] It should be carefully noted, however, that governing factors such as shrinkage, etc., are rather difficult to compute exactly, necessitating an ample allowance on the

[36] A. B. Vattenbyggnadsbyran, Stockholm, Sweden.

[37] "The Design and Construction of Dams," by Edward Wegmann, Eighth Edition, N. Y. and Lond., 1927, p. 162.

[38] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1191.

safe side. Any uncertainty as to the assumptions adopted for a theoretical investigation of this nature should be carefully considered in the light of actual experience on dams already constructed, etc.

The writer would not consider it safe to state that an arch of any required radius is preferable to a straight dam. It is undoubtedly true, however, that an arched dam has a larger factor of safety against ultimate failure than a straight dam of the same cross-section. The arched dam may stand by arch action, even if the cantilever has been broken, provided the abutments are capable of taking the arch thrust. In this there is, perhaps, a nucleus of a rational use of the gravity section, considering the possibility of making less provision for uplift. When doing this, however, engineers should realize clearly that they may have sacrificed some of the factor of safety against failure.

Back pressure on contraction joints or in shrinkage cracks would undoubtedly reduce the effective head on an arched dam. The question is, however, whether it is advisable, without special arrangements, to count upon it for the stability of the dam.

It might happen that full back pressure exists in one joint, but that the next joint is partly or wholly drained. This would evidently involve an unfavorable condition for the block that is subjected to the side pressure. It is questionable, therefore, whether it is consistent with a safe design to count upon the ideal conditions of full back pressure on contraction joints or in shrinkage cracks, unless special measures are taken to seal the joints and the cracks effectively at the down-stream end. It would be exceedingly interesting to know whether such measures have been applied in any case, and how they have been executed.

The writer agrees entirely with Mr. Wiley that the use of any device which offers a very short distance of travel for percolating water in the concrete, should be avoided as far as possible. However, an effective sealing of the contraction joints at the down-stream end tends to concentrate the whole drop in pressure to the down-stream face of the dam and especially to the toe. This may cause deterioration and corrosion of the concrete in that vital part of the dam.

Furthermore, the down-stream seals in contraction joints may lead to unexpected consequences as regards the uplift. The admission of back pressure in the joints should inevitably involve a considerable increase in the allowance for uplift in and under the dam.

If the contraction joints are sealed at the up-stream face, it does not seem reasonable to assume full back pressure on the joints. Apparently, this question has a great bearing on the design. Therefore, it would be of the greatest interest and of the utmost value to have a number of completed dams visited by a committee of experts so as to determine whether or not reliance can be placed on such back pressure. In the writer's opinion it does not seem consistent with a proper design to accept an unsafe assumption on the ground that it sometimes happens to be correct.

An arched gravity dam without support from the arch and with no back pressure on the joints would have a smaller factor of safety against partial failure than a straight dam. The writer has also shown[39] (without advocating

[39] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 784.

the use of the design, however) that a curved dam with a convex down-stream face under certain conditions may be more stable than a straight dam of the same cross-section. This is not a fallacy, because there is always the possibility of draining the joints, so that back pressure shall not occur. If it existed in this case, it would increase the effective head on the dam.

*Uplift In and Under Dams.*—In a homogeneous mass consisting, for instance, of cement or lime, there is probably no uplift, because the forces in each void (as explained by Mr. Wiley) are opposed and cancelled by equal forces in the voids below. If this is correct, however, there must consequently be uplift at a point of perfect contact between the masonry and a rock that is free from seams, because in a tight rock there are no voids below.

As a matter of fact, there must always exist an unbalanced pressure in planes between strata of unequal porosity. Such planes are constituted by the foundation and, to a certain extent, by construction joints or other places of non-homogeneity in the dam.

Uplift conditions do not seem to be the same in concrete as, for instance, in cement or lime, Professor P. Fillunger has shown[40] theoretically that uplift exists in a mass of concrete due to the content of sand and stone. He has also derived formulas for the computation of the uplift in a dam subjected to percolating water.

C. A. P. Turner,[41] M. Am. Soc. C. E. (by letter).—The tendency to build dams of ever-increasing height is statistically shown by Mr. Henny. In general, concrete rather than masonry is best fitted for such structures because of lower cost; and reinforced concrete is preferable to plain concrete. A dam 400 or 500 ft. high presents a structural problem of the first magnitude, requiring for its most economic but safe design ingenuity of a high order, checked by the rigid application of exact elastic theory to the resistance of the materials involved.

*Foundations.*—For the high gravity type of dam the abnormal quantity of concrete required to follow Rankine's view of stability has been reduced by the hydraulic engineer with such increase of toe pressure that it equals or exceeds the shearing strength of softer rock and only a solid ledge of hard rock, such as granite, trap, dolomite, etc., is fit to sustain it.

The customary margin of safety of 100 or 125% in engineering structures has, in the design of high gravity dams, been reduced by the hydraulic engineer to so small an amount that dams with base widths of 66% and 85%[42] of the height, as compared with Rankine's 100%, are now being discussed. Why not revert to the structural engineer's idea of a liberal 100% margin of safety? Why not adopt a base of one and one-third or one and one-half times the height so that safety against overturning would be apparent without computation or argument? Why not incline the up-stream face of the straight dam so that the resultant water pressure will push the dam down on its base, increasing its stability and shearing resistance to sliding, instead of following

[40] "Auftrieb und Unterdruck in Talsperren," by Prof. P. Fillunger, *Die Wasserwirtschaft*, No. 20–21, Vienna, 1929.

[41] Cons. Engr., Minneapolis, Minn.

[42] *Proceedings*, Am. Soc. C. E., January, 1930, Papers and Discussions, pp. 166–174.

the unscientific practice of building a vertical up-stream face with a resultant pressure tending to overturn the dam, to raise the heel, and to crush the toe, thus illogically reducing, instead of increasing, resistance to sliding?

The carpenter millwright of years ago built timber dams applying this reasoning to his construction. The multiple-arch type of dam in which buttress walls at intervals of about 30 ft. support arched concrete plates is one resultant of this line of thought, and such structures have permitted the economic development of irrigation projects that would not have been commercially feasible with the more cumbersome gravity type.

The objection urged by some against the multiple-arch type is that if a single abutment should slip or be undermined then arch after arch would fail consecutively. A further objection is urged against the thinness of the concrete plates, but this objection is based upon disintegration of porous and inferior concrete.

From the construction standpoint buttress walls in the multiple-arch dam cannot carry the great weight incident to the high dam as economically as hooped and longitudinally reinforced columns; nor can the arches be centered from abutment to abutment as inexpensively as a flat slab from column to column.

The writer's opinion as to the most economical type for the long straight high dam is a flat slab or an inclined plate design with a relatively flat up-stream slope, or batter. This slab can be supported by reinforced columns, or struts, battered to coincide with the direction of the resultant of the water pressure and vertical load. With an inclination of the plate at an angle of 40° to the horizontal the base is more than one and one-half times the height.

The quantity of concrete required for such a structure is approximately one-third that required for mass concrete of the gravity type; and when the surface rock can safely carry 20 tons per sq. ft., the quantity of concrete required would not be one-fourth as great. Offsetting the saving in part is the reinforcement and higher grade of concrete used. The margin of safety will be much more than that of the ordinary engineering structures, in order to guard against the damage and loss of life that follows failure.

*Curved Dams.*—This type may be divided into two classes, those in U-shaped canyons and those in V-shaped canyons. In the first class are short high dams between rock walls that are nearly vertical and in which the resistance is predominantly arch action when the height is three to four times the length of the crest. Computation on the assumption that the entire resistance is arch action will lead to a safe structure without excessive waste. On the other hand, with a V-opening and a length of crest two and one-half times the height, the resistance is predominantly a twisting resistance. The down-stream component of the normal water pressure twists the curved plate because the base cannot deflect elastically down stream so as to permit arch resistance. The cross-stream component of the normal pressure gives rise to secondary arch action in which the cross-stream pressure is comparable to the abutment thrust of the true arch. That the resistance is predominantly a twisting resistance was demonstrated in the experiments on the Stevenson Creek Dam.[5] The deflection of the end quarters of the crest was up stream against pressure.

No deflection occurred at the quarter-point, but the central half of the crest deflected down stream.

In masonry structures the old craftsman broke joints in his natural stone masonry, thereby attaining increased resistance approaching that of a monolithic mass. In the artificial stone of the concrete dam this practice has not been followed because of the exaggerated idea of temperature stress presented in engineering handbooks and taught in works on strength of materials.

From observation it appears that the steel stress necessary to restrain the contraction of concrete through a wide variation of temperature is less than one-tenth that computed according to handbook rules. At Moose Jaw, Sask., Canada, a flat slab structure with expansion joints between 300 and 400-ft. centers was inadvertently built with rails not cut where joints were made in the slab. These two rails (65 lb. per yd. in section) restrained the contraction of the slab of 9 000 sq. in. cross-section under a drop of 60° Fahr. After the rails were cut, the joint opened from $\frac{3}{4}$ to $\frac{7}{8}$ in. with a loud report. Ordinary computation would indicate a stress in the rails six times their yield point value and twelve times the strength of the fastenings if the contraction of the concrete were assumed to allow 2 000 000 lb. for the modulus of the concrete, which tested more than 4 000 lb. per sq. in. Considering the steel and the tension which would be required to elongate the steel $\frac{3}{4}$ in. in that length and dividing this by the area of the concrete, the tension in the concrete must have been so small that a review of the basis of ordinary computation is in order.

This method assumes without experimental verification that an elastic material under longitudinal strain expands the same amount laterally as if the longitudinal strain were lacking. Investigation of the thermo-elastic properties of matter by Kelvin indicates roughly that the shift of internal energy of vibration from kinetic to potential, or *vice versa,* represents an amount of energy twice the external work of deformation. Hence, it is logical to conclude that the temperature stress is one-half or less than one-half in the homogeneous material than that which is ordinarily computed by text-book rules. In dealing with the composite mass of concrete and metal the tension in the steel opposes the contraction of the concrete under a drop in temperature, and the steel transmits this tension to the concrete through shear, resulting in a rotation of the direction of the principal tensions 45° to the axis of the steel. It is reduced, therefore, relatively to one-half the magnitude of the restraining tension of the steel and distributed through the section in such a way that, were there diagonal reinforcements in addition to longitudinal, it would be further reduced.

As previously noted, when the two rails were sawed nearly through, the nicked section broke with a bang. The cross-sectional area thus broken, multiplied by the ultimate strength of the material when so nicked, furnishes a definite measure of the contraction stress on the 9 000 sq. in. of cross-section under a drop of temperature of approximately 100° Fahr. The total stress distributed across the cross-section would be, on this basis, less than 90 lb. per sq. in. A contraction force distributed between the longitudinal and the

diagonal steel reinforcements and the concrete itself leaves a tension of less than 40 lb. per sq. in. in the concrete matrix developed by the drop in temperature of 100° Fahr., which is an amount too small either to crack or to check the concrete.

This fact accounts for the lack of difficulty which the writer has had in building flat plate dams 3 000 ft. in length without expansion joints, and bridge floors 500 to 600 ft. long without any provision whatever, under temperatures ranging from 100° above to 50° below zero. It indicates the practicability of the monolithic concrete dam when properly reinforced, so that the full resistance of a monolithic mass may be secured without serious checking or cracking of the concrete. The advantage of the well-reinforced monolith lies in its toughness, as illustrated by the example of the failure of a water tank.[43]

Bridge engineers a generation ago discarded the use of plain concrete because reinforced concrete presents greater toughness and dependability and because a smaller body of reinforced concrete may be used more economically. This practice of the bridge designer, which is the result of extended experience, may well be followed in the design of concrete dams for greater safety and dependability.

Unscientific computation of the maximum tension in the concrete has been presented repeatedly in Society publications, based upon the futile effort to apply the ordinary or approximate theory of flexure (suitable only for determining the maximum fiber stress in a long cantilever) to a short section of a dam having a length only a fraction greater than its thickness. Exact theory which takes into consideration shear strain is essential to practical accuracy and rational conclusions.

Resistance to external shear force is found (dependent upon the relative thickness to span length) to be several times greater per unit of cross-section with continuous and restrained beams and slabs than by the erroneous assumptions on which the complicated ordinary theory of flexure is based.

Although the correct equations for the statical equilibrium of moments was taught sixty years ago,[44] these principles have been so little understood or have been so disregarded by the majority of present-day engineers that computation of curved dams and flat plates supported upon columns or beams differs widely from the simple exact solutions resulting from their rigid application.

The writer's views may be summarized as follows:

1.—For the high dam reinforced concrete rather than plain concrete should be used from the standpoint of economy and safety.

2.—The inclined plate has an advantage in reducing the pressure on the base to approximately one-third that of the gravity type and of reversing the distribution of maximum pressure, so that the maximum pressure occurs at the heel and the minimum pressure at the toe, thus insuring stability.

[43] *Proceedings*, Am. Soc. C. E., January, 1930, Papers and Discussions, p. 170.

[44] "Natural Philosophy," by Thomson and Tait.

3.—Under settlement, the water pressure with the inclined-plate dam forces the column down upon its bed, and, although the slab may be cracked because of such settlement, it will still carry the load because the twisting resistance of the plate is not destroyed by checking from the top to the bottom.

4.—For the long high dam, the inclined plate is the most economical type, and its stability against overturning is apparent without computation or argument when the base is one and one-half times the height. Such a liberal base adds to the resistance against sliding, and the water pressure itself tends to increase this stability instead of reducing it as in the gravity type.

5.—For the relatively short dam on a rock base in a V-formation the curved dam may cost less than the plate structure; but if the curved dam is built the surfaces should be substantially cylindrical with flatter curvature at the ends and the sharpest curvature in the middle half. Such a dam with a length of crest two and one-half times the height should be computed for its predominant torsional resistance instead of as an arch. It should be built as a monolith and reinforced for temperature stresses.

6.—The curved dam is suitable only where the base presents a ledge of hard solid rock.

7.—The reinforced plate is suitable to dams far higher than any yet proposed. With column spacing of 30 ft. for a 500-ft. dam, the diameter of the lower columns will be approximately three-eighths to one-half their distance center to center; and the bracket heads will furnish a complete sub-arch from column to column where the pressure is greatest.

Were the dam designed with no greater margin of safety than the ordinary multiple-arch structure, the reinforcement could be treated as temperature ties for the thicker panels. Conservative practice, however, will dictate the computation of the steel on the exact theory of flexure, so that the margin of safety will be greater than that in bridge design.

In view of the enormous damage and loss of life that attends the failure of a high dam, why not make the structure so tough that it would be difficult to crack up with dynamite, instead of so fragile that a little leakage and undercutting is sufficient to cause it to crumble and fall apart, letting loose a deluge as in the case of the St. Francis Dam failure? There is no excuse for a high dam that does not embody such toughness and safety, since the cost is much less than that of the gravity type and the work may be executed with greater facility and rapidity.

F. W. Hanna,[45] M. Am. Soc. C. E. (by letter).—The Symposium on High Dams, as presented by the authors, is fundamental rather than exhaustive. It forms, therefore, basic data for elaborating more complete information from which to develop principles of dam design. In this respect it is a useful contribution.

The question of what is a high dam has not been answered in the Symposium; and, indeed, it cannot at this time be subject to answer in a single figure for any type of dam or for dams as a whole. Table 1 gives the highest dams constructed or under construction, at the present time (1930).

[45] Chf. Engr. and Gen. Mgr., East Bay Municipal Utility Dist., Oakland, Calif.

These data represent the present extremes of practice, and indicate to the writer somewhat of the relative future heights of the various types of dams. It now appears that the arch and the gravity types are well in the lead in this respect. The second highest gravity dam of any type in existence is the Pardee (Lancha Plana) Dam, 358 ft. from base to top, and the second highest arch dam is the Pacoima Dam, 375 ft. from base to top. The San Gabriel and Boulder Canyon Dams, both of the masonry gravity type, have been projected for still greater heights, the former for 500 ft. and the latter for 700 ft. These dams indicate the possible future trend of gravity dam heights. However, the San Gabriel Dam has been abandoned on account of a defective foundation, and the Boulder Canyon Dam has not been started and may be changed in design before it is built.

TABLE 1.—HIGHEST DAMS OF VARIOUS TYPES

Theoretically, both earth and rock-fill dams on suitable foundations may, by proper dimensioning, be made very high; but their lack of resistance to disintegration on overtopping, their liability to destruction from leakage, and their great bulk for their height, due to increasing side slopes with increasing heights, will probably never permit them to rival in height the arch or gravity masonry dams.

The buttress types are generally built with comparatively thin sections requiring reinforcing steel for stability in design, which may limit their lives too much for high, expensive, important dams. Thin sections are also poor resisters of seepage, frost, and earthquakes. Consequently, the buttress types are not likely to be the rival high dams of the future. This, of course, does not limit their usefulness for relatively low dams.

Through the elimination of the earth, rock-fill, and buttress types for the various reasons cited, the high dams of the future are likely to be, as they are now, either the gravity or single arch type. As to which of these will be the final pinnacle of height depends on the natural formation of canyons. The gravity type will no doubt lead for wide, and the arch type for narrow, canyons. The limiting heights of these dams on hard impervious rock foundations will be determined by the allowable working stresses in good concrete; and the dam that can come within these stress limits at least cost will ultimately be chosen. In the very high dams of these two types, stress limitations now come into play; but it is certain that stress allowances will be greatly increased with better concrete mixtures and manufacture; perhaps they may be doubled in the near future.

The arched gravity dam is superior to the straight gravity dam only in cases where the arch length is not too great, where the canyon walls will resist pressure, and where the foundation contours make it the cheaper. It is evident that no advantage results from arching the gravity type dam when the canyon side-walls are not suited to taking arch thrust. In very wide canyons no benefit is derived from arching the gravity dam because excessive deflection or buckling of the arch slice may result if the slenderness ratio is too great. When the height from foundation to crest decreases from the center toward the abutments the greater deflections of the longer cantilevers throw torsional stresses, sliding tendencies, and overturning moments into the shorter cantilevers toward the ends of the dam. The arch resistance helps the shorter cantilevers to absorb these loads. In the case of a straight gravity dam these loads can be resisted only by increased sections. That arch action actually takes place in an arched gravity dam is clear from the effects of cantilever deflection, due to water load and soaking of the up-stream face. In the computation of the stresses in the arched gravity type of dam by the usual method of taking a vertical slice of one unit width, at the up-stream face, the parallel plane theory should generally be used because such a slice between radial planes cannot slide or rotate out of place independently and this method of calculation does not give credit to the full weight of the material in the dam.[46]

For narrow canyons with sound rock side-walls, the arch dam is superior to the gravity dam on account of economy of materials and greater factor of safety. That the volume of the former is much less than that of the latter is evident. The factor of safety of a gravity dam against sliding may generally be only a little more than 1, and seldom more than 2, whereas that of a well-designed arch dam of the type tentatively suggested by the writer[47] for the Pardee Dam is 5 or 6, or more. In addition to the usual factors of safety provided for shear and compression stresses, such an arch dam has unknown additional factors of safety due to torsional resistance, to transference of stresses to the foundation by the shortest route, and to a limited degree cantilever beam action. That torsional stresses exist in arch dams has been pointed out by the writer.[48] These stresses and the corresponding resistance may be computed in each arch slice by considering the resistance to twisting of the voussoirs in it as the arch deforms under its load. The effect of arching by the shortest route to the abutments is very difficult to ascertain, but that it often exists to a considerable degree is certain. Neither the trial-load method nor the single-center cantilever method of computing the cantilever beam resistance is very reliable because of incorrect basic assumptions. Moreover, the dry down-stream face and the wet up-stream face may produce deflections in the cantilevers that bring arch action into play and relieve the cantilevers of their loads. The fear of tension in the up-stream face of an arch dam designed as suggested is not well-founded, as

[46] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), pp. 799–808.

[47] *Engineering News-Record*, March 15, 1928; *Western Construction News*, May 25, and June 25, 1928; and February 10, 1929.

[48] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), pp. 1246–1250.

cracks produced by such tension only extend into the dam a short distance and the uplift is prevented partly, if not altogether, by water soaking. This is not true of tension in the up-stream face of, and uplift in, a straight gravity dam, where increased overturning resistance is called into play. The arch dam is now, and is bound to be, a strong rival in the future for the position of maximum height in masonry dams.

Pressure grouting has been used with splendid success, both in the foundations and in contraction joints of some of the high dams now constructed, and will be used quite probably in all high masonry dams in the future. It is the writer's opinion that no high dam either of the arch or gravity type should ever be constructed without a complete grout curtain under the heel, put in under the highest practicable pressure without disturbing the rock strata of the foundation or the contact of the dam with the foundation rock.

It has also become quite general practice to construct both arch and gravity dams with vertical construction or contraction joints at intervals perpendicular to the up-stream face of the dam and sealed with metal water-stops. These joints should also be grouted under strong pressure to insure water-tightness in all high masonry dams and also arch action in the arched gravity dam and the arch dam. There is no difficulty in securing thorough distribution of the grout in the joints when they are properly designed.[49]

The protection against uplift in a high masonry dam by the addition of a drainage system to the grout curtain already discussed, seems to be gaining ground. The drainage system for a gravity dam should be made to consist of a cut-off trench near the up-stream toe, connected by tile pipe with a series of wells arranged to discharge into an inspection gallery of such proportions as to permit drilling. For an arch dam, drainage holes should be drilled from the down-stream face of the dam into the foundation to points near the up-stream face, thus relieving pressure.

It is also being appreciated that in high gravity dams of considerable thickness cracks are liable to occur parallel to the faces of the dam and it has been proposed to place contraction joints in such dams to control these shrinkage cracks. Whether this can be done without special treatment to care for the stresses is not yet certain because continuity of stresses from heel to toe and top to base of these dams requires continuity of resisting material. In the case of a smooth contraction joint parallel to the down-stream slope of the dam, the slab down stream from the joint may, if the joint opens, crack near its middle under its load, and fall against the adjoining concrete; or it may act as a column or strut tending to overturn the top of the dam up stream, thus producing tension on the horizontal planes.

H. F. DUNHAM,[50] M. AM. SOC. C. E. (by letter).—There is a measure of assurance in Mr. Wiley's discussion of the effects of contraction in the curved gravity type that must be gratefully regarded by those who design high dams. The same confidence shows in the reference to uplift. If

[49] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), pp. 799–809; *Engineering News-Record*, March 21, 1929.

[50] Civ. and Hydr. Engr., New York, N. Y.

up-stream, vertical contraction cracks are not a serious weakness, and if uplift can be greatly lessened through the absence of smooth horizontal surfaces, two features in construction will seem less formidable.

While the writer's approach to the question of uplift as stated in an earlier discussion[51] differed from that of Mr. Wiley, the result was not at variance with his conclusions. There may be noted, too, the similarity with respect to saturation of deep quarry rock and the concrete in a remaining part of the St. Francis Dam.

To avoid metal seals, the writer, in 1928, proposed the use of heating units (electrical, steam, or hot water), to be placed near each face of a dam, but not too close together. The pipes or pipe lines should be easily drained; they should be free to expand; and all should be connected to one source of heat. Used in, or prior to, cold weather the heat would be distributed and stored to offer a barrier to frost by increasing radiation. The involved principle of heat transference would be similar in some respects to the charge of a storage battery from a small unit. The slow increase in heat would be available when needed. The expense may appear favorable if set against the cost of extra masonry useful, in part, as a blanket to protect that section of a dam above the normal up-stream water elevation.

LARS R. JORGENSEN,[52] M. AM. SOC. C. E. (by letter).—Much discussion has taken place recently as to the exact action of a gravity dam arched in plan. Mr. Wiley favors an arched gravity dam and evidently believes that under all conditions such a dam would have the resistance of the arch in addition to its weight. His conclusion that "the contraction joints of an arched gravity dam do not prevent arch action" needs considerable explanation. Most large arched gravity dams built—such as the Exchequer Dam in California—have open contraction joints in late winter. Therefore, it is physically impossible for arch action to be present in the winter when this dam supports full water pressure.

Such a dam, therefore, can not have a larger factor of safety under all conditions than a straight dam of the same section; most likely it has a smaller factor. If it had a larger factor of safety the St. Francis Dam would probably still be standing because it might not then have developed tension in the up-stream face. The Exchequer Dam has considerable tension in the up-stream face in the winter when it can receive no help from arch action. It is built on a good foundation and, therefore, apparently can take care of this tension, but it is not correct under such conditions to call it a gravity dam.

There are enough uncertainties in connection with the design assumptions and the actions of gravity dams to demand a base width of not less than 75% of the height for medium high dams and considerably more for the higher dams. There is no satisfactory substitute for weight in a gravity dam.

Mr. Wiley makes the statement that "at present the arched gravity type of masonry dam is slightly in the lead with respect to height". This is not in accordance with facts. The three highest dams, holding back the greatest depth of unsupported water load are arch dams, such as the Drac River Dam

[51] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 246.
[52] Cons. Hydro-Elec. Engr., San Francisco, Calif.

in France, 430 ft., the Pacoima Dam, 365 ft., and the Diablo Canyon Dam, 363 ft. There is no reason why this type should not or could not be built at least as high as any gravity dam on sites where it would fit, and be safer and cheaper. The safety of gravity dams, in comparison with other types, especially single arch types, has been greatly over-rated in the past. For very high arch dams it would be good engineering to use higher stresses than those now generally acceptable, say, up to a maximum compression of 1 000 lb. per sq. in., and to ensure that no concrete would go into the dam of less ultimate crushing strength than 4 500 lb. per sq. in.

This would not be at all difficult. Such a dam would have a factor of safety in excess of that of any high gravity dam that would be commercially feasible to build. Besides, in the majority of cases the arch dam would be much cheaper.

WILLIAM P. CREAGER,[53] M. AM. SOC. C. E. (by letter).—With particular emphasis on the outlook for the future, the writer has often wondered if the theory of design, as applied to existing dams, is adequate for very high dams. The tendency is for higher dams, and it is now proposed to build a dam 700 ft. high, or nearly twice as high as the highest dam in existence. The Quebec Bridge failure taught a lesson in regard to the utilization of theories for large members or structures which have been proved adequate only for small members. Has this lesson been well learned by the designers of dams?

As a word of caution, the writer desires to call attention particularly to two features of design which, in his opinion, are in doubt for high masonry gravity dams.

The force required to move a block of stone or concrete on a like surface has been determined by tests to lie between 55 and 70% of its normal weight. Actual coefficients of friction in a large number of dams have been adopted within this range. Therefore, without consideration of the shearing resistance due to roughening of the foundations and adhesion of the concrete to the rock, a factor of safety of only 1.0 has been provided. It has been assumed, however, that this additional resistance to movement, termed "shearing resistance" in this discussion, is enough to provide sufficient margin of safety. Is this margin sufficient for very high dams? Assuming homologous triangular sections, the total shearing resistance of the foundation varies as the height of the dam, whereas the sliding force of the impounded water varies as the square of the height. Therefore, the shearing resistance is seven times as effective in a 100-ft. dam as it is in a 700-ft. dam. In other words, a shearing resistance of only about 30 lb. per sq. in. is necessary for a factor of safety of 2.0 in a 100-ft. dam; but, in a 700-ft. dam, 7 times 30, or 210 lb. per sq. in., is necessary. Actually, a slightly less shearing resistance than 210 lb. would be necessary owing to the greater spreading of the base of a 700-ft. dam to limit compressive stresses.

In the case of resistance to overturning, present theory requires that the resultant for reservoir full must lie within the middle third, because otherwise

[53] Vice-Pres. and Chf. Engr., Northern New York Utilities, Inc., and The Power Corporation of New York, Watertown, N. Y.

there will be tension in the base with the resulting tendency to open cracks and admit full head-water uplift and progressive failure by overturning or sliding. The elastic theory varies this rule somewhat, but is outside the present argument.

As many dams have been designed with the resultant close to the extremity of the middle third, it must be considered, therefore, that tension adds the necessary margin of safety. As the total resisting moment of this tension varies as the square of the height of the dam and the overturning moment as the cube of the height, the resisting moment of tension in the base is seven times as effective in a 100-ft. dam as in a 700-ft. dam.

If a dam, with the resultant at the down-stream extremity of the middle third, is assumed to have a factor of safety of 1.0, neglecting adhesion of the dam to the foundation, it requires a tensile strength of about 100 lb. per sq. in. in a 100-ft. dam and 700 lb. in a 700-ft. dam, to provide a factor of safety of 2. As in the previous case, the required tensile strength would be somewhat less than 700 lb., due to greater spreading of the base in a 700-ft. dam.

The foregoing is not intended to be an exact analysis of the subject, but is presented only to indicate that, under the generally accepted practice in the design of dams, a very large dam has a much lower factor of safety than a small one. It seems to the writer that engineers are treading on dangerous ground if they do not apply to the design of very large dams a careful consideration of those factors which, in small dams, are neglected except with the thought that they provide an additional margin of safety.

L. F. HARZA,[54] M. AM. SOC. C. E. (by letter).—The gravity concrete dam, whether straight or arched in plan, probably now commands the confidence of the majority of engineers to a higher degree than other types of high dams. It is open to serious doubt whether this confidence is fully justified, and whether existing rules of design can be safely extended to much greater heights without far more knowledge of behavior than is now available.

The factor of safety generally used is much less than factors used in other engineering structures, and is not sufficient to inspire confidence when one considers the many uncertainties, such as possible internal longitudinal cracking; possible tension at the heel; uncertainty as to amount of uplift along the bottom and horizontal construction joints; effect of internal pressure in the concrete; and the fact of reduction in factor of safety against sliding as the height of the dam increases while maintaining the same factor against overturning. The last item has been discussed elsewhere.[55]

The principle of keeping the line of pressure within the middle third of the base, assumes a straight line distribution of pressure from heel to toe. This is an assumption of very questionable accuracy, in a structure having the base width of a high dam, with interior temperatures differing from those at the surface, and with a somewhat flexible toe carrying the heaviest load to a foundation of perhaps not uniform resistance. This assumption ignores several uncertainties that have been pointed out by other writers. For example, it has not been possible, or at least practical, in other concrete structures to

[54] Cons. Engr.; Pres., Harza Eng. Co., Chicago, Ill.

[55] See p. 197.

build them monolithic for a length equal to the thickness of a high concrete dam without contraction cracks, and such cracks, if approximately vertical, would reduce the effective base width of the dam. Contraction cracks might originate from shrinkage due to overheating during construction, from drying out, from seasonal temperature changes, and from stress.

In the writer's opinion, the middle-third theory is so superficial a principle that confidence in gravity dams can be based principally on reasonably satisfactory past behavior, rather than upon theory. The result is to place rules of design on inductive rather than deductive bases, and to make the design of gravity dams an experimental art, rather than a science. In fact, engineers are not justified in referring to the middle-third method as other than a "rule-of-thumb" procedure, the best support for which is not the mathematical basis, but rather the fact that few failures have occurred.

Current practice in gravity dam design is none too safe, and, in fact, a grave responsibility rests upon the engineer who goes much beyond existing precedent in the height of gravity dams without a far greater knowledge of their internal behavior, and much better control of temperatures and uniformity of concrete, than is now possible.

However, the future is promising because it would seem that engineers are now beginning to learn something about gravity concrete dams. Intensive thought and research is now beginning to focus on this problem, so that the hope may be entertained that engineers are entering an era of research and of scientific study of dam design and the equally important factor of field control. It is probable that, as a result, the old methods will be largely discarded in favor of an analysis involving other than straight line distribution of pressure from heel to toe and other refinements.

There are possibilities of artificially controlling the placing temperatures and the curing temperatures; and several other precautions may be observed, which may assist in building dams that will perform more nearly according to the so-called theory.

In the field of power engineering there has been an ever-decreasing cost of steam energy coincident with an ever-increasing cost of hydro-electric energy; this fact is forcing upon the hydro-electric engineer the exercise of the utmost economy in the design of dams, which form such a large proportion of the cost of a hydro-electric project. Hence, the need for consideration of the merit of earth-fill dams, whether by the dry or the hydraulic method, combined earth and rock-fill dams, rock-fill dams, arch dams, multiple-arch dams, or other types, which may save an initial cost under certain favorable conditions.

An earth dam, well built and constructed under equally good conditions of foundation and available materials, undoubtedly compares favorably in permanency and safety with a concrete dam, when once it is successfully completed. In fact, when once completed, the earth-fill dam is subject to much less in the way of uncertainties than the writer has pointed out in connection with the gravity concrete dam; and it has given as good an account of itself in actual service.

Earth-fill or other loose-fill dams have a well recognized advantage when constructed on soft material or defective rock foundations, because they can usually be accommodated to these conditions, whereas a concrete dam would require very deep excavation, pile, or caisson supports, and often could not be built at all.

A loose-fill dam requires the protection of an ample spillway, and is, therefore, best adapted to situations where a natural ridge is available for large spillway capacity at minimum cost.

The principal uncertainty with an earth or other loose-fill dam is during the process of construction in connection with diversion of the river. Few, if any, earth dams are built, or could be built economically, if provision must be made for diversion during any stage of construction of the maximum flood which might occur on the stream in a long period of years. Construction schedules are, therefore, more important in this case than for concrete dams, and must be very carefully studied and rigidly adhered to in order to permit the work to reach a stage, during a low-water season, which will insure sufficient head to divert the river through culvert or tunnel when the flood season arrives.

Earth dams may be said to be most ideally adaptable when of small volume, so that they can be built between flood seasons, thus avoiding expensive diversion work. They are well suited for small drainage areas where ample diversion provisions would not involve excessive cost. With equivalent dam site topography and foundation conditions, an earth dam would cost much more on a large stream than on a small one, because of the greater cost of diversion; or otherwise a greater hazard would be involved in its construction, if provision was not made for equally safe diversion. The same may be said of a dam of any loose material, such as a combination earth and rock-fill or a rock-fill dam.

In the case of the proposed Boulder Canyon Dam, however, the same problem of diversion is involved, because of the depth of excavation required to reach satisfactory foundation, and this excavating operation must be protected from overflow throughout one or more flood seasons. When a concrete dam is once brought up to river-bed level, however, the hazard of flood during construction is less than with dams of loose material, unless ample diversion capacity is provided for the latter.

A. FLORIS,[56] ESQ. (by letter).—In his paper Mr. Wiley deals briefly with the relative merits of the various types of high dams. In doing so he arrives at certain conclusions which are at variance with the views commonly held by hydraulic engineers. The present discussion will be confined merely to the action of water in the pores of gravity dams.

The problem of water pressure within a gravity dam has been attacked successfully by Professor Paul Fillunger.[57] His treatment of the subject is based on a rigorous mathematical analysis the results of which agree substan-

[56] Civ. Engr., Los Angeles, Calif.

[57] "Der Auftrieb in Talsperren," von Dr.-Ing. Paul Fillunger, *Oesterreichische Wochenschrift für den öffentlichen Baudienst*, 1913, Nos. 31, 32, 33 and 34; "Neuere Grundlagen für die statische Berechnung von Talsperren," von Dr.-Ing. Paul Fillunger, *Zeitschrift* des Oesterreichischen Ingenieur- und Architekten-Vereins, 1914, No. 23; also, reprint.

tially with the tests. His findings are contrary to the opinions advanced by Mr. Wiley, so that it is worth while to compare them.

Mr. Wiley reasons that uplift can be produced either in a horizontal seam in the rock, or in an open horizontal construction joint in the dam itself. Therefore, if the dam has no such planes of weakness, no consideration should be given to the possible action of uplift. On the other hand, the water pressure within the pores of the concrete exerts no influence on the static equilibrium of the structure. This view is supported by calling attention to the fact that the pressure in the pores is equal in all directions, so that to an upward pressure within a pore is opposed an equal pressure in the adjoining pores, causing all forces to be cancelled. The fallacy of these statements can be seen by referring to Professor Fillunger's scientific investigations.

If the pressure in the pores of a body is the same in all directions, but can vary from pore to pore, it is evident that no uplift can be produced. However, if the water meets greater resistance in one direction than in another an uplift pressure invariably will result. This case is present in a gravity dam, in which some parts are more porous than others. The uplift in a concrete dam depends, therefore, on the porosity of the aggregates and of the cement paste, respectively. As the difference in the porosities of these two materials in a dam is comparatively high, it follows that uplift cannot be neglected.

Since a rigid body submerged in an incompressible liquid will have an equal pressure upon its surface in all directions, the resultant of the weight of the body and of the total pressure of the liquid, acting upon it, will be directed upward or downward, depending on the relative magnitudes of these two forces. On the other hand, if the water is surrounded by a rigid body, the same resultant acts on the surface of this body but has an opposite direction. This last case is of importance in the application of this law to gravity dams. In both cases the forces acting on a surface are replaced by forces acting in space, or, in other words, by forces denoting mass.

The field intensity, $p$, of the pore pressure in the interior of a gravity dam is smaller than the field intensity of the water in the reservoir, that is, the hydrostatic head, which is given by,

$$p_0 = \gamma\, h \qquad (3)$$

in which,

$\gamma$ = specific weight of water; and
$h$ = height of water level measured from the point under consideration.

At the down-stream face of a porous dam the field intensity of the pore pressure will be necessarily zero, or,

$$p_2 = 0 \qquad (4)$$

Near the up-stream face the field intensity of the pore pressure will be a little less than the hydrostatic head, or,

$$p_1 < p_0 \qquad (5)$$

From this expression it follows that the water in the pores of a dam will be in a state of steady flow. Assuming that the dam is water-tight at the down-

stream face as well as at the base, the infiltrating water will reach equilibrium when all pores in the concrete are filled with water. In this case the intensity of the pore pressure will be the same as the pressure in the reservoir at equal elevations. In an ordinary case, however, in which neither the dam nor its rock foundation is water-tight these lines of equal intensity or gradients will deflect toward the base and toward the down-stream face because of the variable intensities of the pore pressure (Fig. 8).

If a sufficiently small portion of the dam with the volume, $v$, is considered, then the resultant, $P$, of the water pressure on the walls of all the pores of this portion, will be expressed (according to Professor Fillunger) by,

$$P = (\mu - \nu) \frac{\partial p}{\partial z} v \qquad (6)$$

in which,

$\frac{\partial p}{\partial z}$ = gradient of pore-pressure,

$\mu$ = coefficient of porosity of aggregates; and

$\nu$ = coefficient of porosity of cement paste.

By dividing both sides of Equation (6) by the volume, $v$, the pore pressure per unit of volume will be obtained.

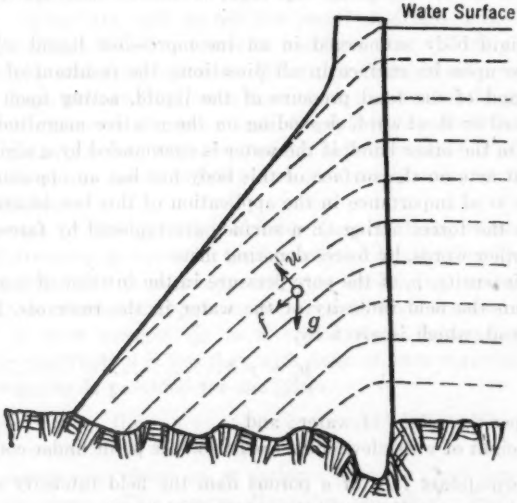

FIG. 8.—GRADIENTS OF PORE PRESSURE.

Since the porosity of the aggregates is usually less than the porosity of the cement paste, it is evident from Equation (6) that the pore pressures of this small portion will have a negative resultant. Consequently, within a dam there is always present a force with a direction opposite to that of the weight of the water. This is, however, none other than the uplift pressure itself.

Assume, for example, that it is possible to build a gravity dam with cement, but without the addition of aggregates; then, obviously, $\mu = \nu$, and Equation (6) becomes $P = 0$. In this case, therefore, uplift cannot be produced in the dam. In ordinary cases, however, the consideration of uplift in the stress analysis of gravity dams should never be omitted in spite of Mr. Wiley's assertions to the contrary. If cobblestones are to be used, this consideration is rendered more imperative, due to their larger size.

The steady flow in a gravity dam caused by the difference of pore pressure in the dam and the hydrostatic head in the reservoir will be maintained by the frictional resistance of the water on the walls of the pores. This resisting force was determined by Professor Fillunger and was found to depend on the porosity of the aggregates, on the gradients of the gravitational field (weight), and on those of the pore pressure, respectively. Therefore, within a gravity dam that is exposed to water pressure there are two forces acting, besides the weight, $g$. These are, the uplift, $u$, and the frictional resistance, $f$ (Fig. 8). The weight is an actual force of mass with a vertical direction, the uplift is normal to the gradients of the pore pressure, and the frictional resistance is perpendicular to it. Consequently, the uplift can be considered as a normal stress, while the frictional resistance corresponds to the shearing stress. The direction of the uplift force is always opposite to that of the weight, while the frictional resistance often, but not always, has a direction the same as that of the uplift (Fig. 8).

As stated previously, the gradients of the pore pressure are inclined toward the down-stream face (see Fig. 8). Therefore, Dr. K. Kammüller has suggested omitting the horizontal component of the uplift and the entire frictional resistance.[58] By plotting the vertical components of the uplift in a horizontal section, a pressure diagram will be obtained which, in a triangular dam, is approximately a similar triangle with the zero pressure at the down-stream face. At the up-stream face this pressure is equal to the hydrostatic head.

This simplification is not quite correct, because the frictional resistance acting along the inclined gradients of the pore pressure has also a vertical component. This component, depending on whether it acts upward or downward, will make the uplift greater or smaller. However, this somewhat crude simplification of the rigorous theory indicates clearly, that the triangular distribution ordinarily assumed, of the uplift in the interior of a gravity dam, is not based entirely on arbitrary assumptions but that it has to a certain extent a scientifically justifiable meaning. It has nothing to do with the opening of a joint, as Mr. Wiley is inclined to assume, but it is the necessary consequence of the pore-pressure distribution in the structure itself.

The foregoing theory explains in a natural way the mechanical action of water in the pores of a dam and is exact and free from assumptions. It is true that the analysis depends largely on the properties of the materials used in the construction of dams and of their rock foundation for which the various coefficients of porosity, etc., must be known in advance with a reasonable

[58] "Die Theorie der Gewichtstaumauern unter Rücksicht auf die neueren Ergebnisse der Festigkeitslehre," von Dr.-Ing. K. Kammüller, Berlin, 1929, p. 13.

degree of accuracy. However, these are problems which confront the engineer in all his activities.

In order to determine whether the water pressure exerts a bursting action within the pores of a material by overcoming its tensile strength a test specimen can be subjected to water pressure of equal intensity and, at the same time, to a pull acting along its longitudinal axis.

Rudeloff, Panzerbieter, and Professor Fillunger tested cylinders of cement mortar to failure by an axial pull.[59] In these specimens water was forced into the pores. In some specimens this penetration was prevented by means of a rubber membrane. Other specimens were subjected to a water pressure on the outer face of the cylinder. This outer surface in some specimens was also protected by a membrane; in other specimens it was not. In all cases the water pressure was raised to a certain limit and then the axial pull was increased until the material failed. In addition to these, other specimens were tested by an axial pull only without subjecting them to a water pressure.

In these tests it was found that by increasing the water pressure the decrease of the tensile strength of the material was very rapid so that under a pressure of 8 to 10 atmospheres, it was practically zero. If the results of these tests were correct, then, as Professor Fillunger states,[60] gravity dams higher than 250 ft. could not be safe, because a material with zero tensile strength will also have an uncertain compressive and shearing resistance.

The reason for this apparent difference between tests and experience is easily seen if it is realized that each of the specimens was prepared in four horizontal layers perpendicular to the axis of the cylinder. Obviously, these planes were the points of weakness. Between these layers the cement mortar was very porous so that it resisted uplift very little, while in the remaining more dense and sound parts of the cylinder the resistance was considerable. This unequal distribution of the pore pressure evidently caused the failure.

Sometimes the failure of a porous material subjected to water pressure in all directions is interpreted as being due to the bursting action of the water in the pores of the body under pressure.[61] According to Professor Fillunger, in such cases the rupture can be assigned to other causes than tension.[62] It is very probable that the release of the water pressure was too rapid so that the water in the inner pores remained under high pressure, while in the outer pores the pressure was reduced considerably. The abrupt change of the pressure within the different parts of the body causes an unequal pressure distribution which results in failure by tension.

Specimens of standard briquettes consisting of the porous Portland cement mortar, less porous slag-cement mortar, and non-porous sealing wax, were subjected by Professor Fillunger to a water pressure in all directions of 100

to 200 atmospheres, respectively.[63] Some specimens were tested without being under water pressure. Simultaneously, a steadily increasing axial pull was applied by the aid of a level arm, exactly as in testing cement mortar briquettes.

In all cases no appreciable changes in the tensile strength of these specimens of different porosities could be observed. The water penetrating into the pores of the body did not produce a bursting action, because otherwise under increasing water pressure the tensile strength of the material must decrease correspondingly.

Professor Fillunger's theory shows that the water pressure penetrating into the pores of the dam produces uplift and friction. The respective vectors of these forces must be combined, analytically, or by the aid of a funicular polygon, with that of the weight of the dam in order to determine the stresses produced by the water in the reservoir. It is obvious, therefore, that the water pressure in the pores of the dam is an important item which cannot be neglected in a correct analysis of stress. Consequently, Mr. Wiley's claim that stresses are not produced by the action of the water in the pores of a gravity dam—not being sustained by theory and tests—cannot be accepted as correct.

JOSEPH WRIGHT,[64] M. AM. SOC. C. E. (by letter).—During two years since 1928 dams and their safety have occupied a prominent place in engineering literature and in engineering thought. One question which has aroused some discussion and has brought out definite opinions from a few is that of initial arch resistance of arched gravity dams. Too many unknown quantities are involved in this question to warrant much confidence in a mathematical analysis; it can only be settled by observations and tests upon existing dams. Such an analysis as is possible may be somewhat enlightening, but it also serves to emphasize current ignorance on the subject in the lack of established facts to substitute assumptions founded upon more or less far-fetched inferences. Why not go at the question in a practical way? Core borings with the drill following the joints between successive blocks, and temperature readings within the hearts of well-seasoned dams, would throw much light on the subject, and other inexpensive tests could be devised that for all practical purposes would settle the question.

Little is known about the temperature changes in the heart of a thick dam; less is known about the effect and extent of water-soaking of the concrete. Engineers are equally ignorant as to the effect of the usual method of construction, that is, the casting of alternate blocks between blocks that have hardened in air, and have given up at least a small part of their chemical heat; and they know little or nothing as to "plastic flow", or "permanent set." Besides, what they know of the modulus of elasticity of concrete is worth little upon the assumption of its uniformity in a dam. Why, therefore, attempt to juggle figures that mean so little?

[64] Chattanooga, Tenn.

The fact that the St. Francis Dam, built without vertical construction joints (as a monolith), cracked, is not conclusive to the writer. It has been well established by the "post mortem" that the abutments were incapable of sustaining heavy thrusts. This, and the fact that the dam was built as a monolith, would predicate a behavior different from that of dams constructed in the usual manner between competent abutments.

As in most questions of controversy, however, much can be said on both sides. Certainly, the St. Francis Dam should not have been built as an arched dam, with or without compensation for the convergence of radial planes, because of incompetent abutments, and its rather great length; although from all that is now known about it, it would have failed just as surely had it been so compensated. Yet no reasonable man who has seen their foundations and profiles will say that such dams as the Arrowrock, the Exchequer, and some others which have been constructed in narrow canyons, are unsafe by reason of the lack of compensation for the convergence of the radial planes; nor would he say that a straight dam of a gravity section presented less hazard as to ultimate failure. That would appear to be the crux of the question—fit the dam to the physical conditions of the site. It is well understood that a narrow canyon having competent abrupt walls is the only suitable site for a single arch of any description. Accepted principles of dam design are rooted in meager knowledge, yet it is feared that this fact is too often overlooked.

In the analysis of the gravity dam, designers know the pressure upon its face; they know, approximately, its weight; and exceedingly roughly they know the strength of concrete made under certain ideal conditions—just the bare skeleton of the problem. The remaining factors have to be assumed; yet they talk about factors of safety as if they were known definitely. In the analysis of the arched dam the engineer's confidence in reaching correct conclusions from false premises through the medium of clever mathematical gymnastics approaches the sublime! He starts with the assumption that concrete is a homogeneous material, uniformly elastic, and that it behaves uniformly under the influence of temperature changes—all of which is known to be false, or to say the least, decidedly inexact. He forms certain fundamental equations as to stresses based upon fallacies, or inexact theories of arch resistance. Then, making certain convenient assumptions with a view of simplifying the solution, he blandly proceeds to compute the stresses in all parts of the dam, ignoring the fact that an arched dam is not a true arch in any sense, and that in no two dams having different profiles would the stresses be at all comparable!

Within the last few years the tests upon models and upon the Stevenson Creek Dam, supplemented by measured strains in existing dams, have cleared the problem of the arched dam somewhat and designers now need not labor wholly in the dark; but more than anything else these tests have shown that previously accepted theories gave results widely different from the facts, and that engineers must rely largely upon models and tests of existing dams to arrive at an approximately correct design.

In considering the stability of dams, therefore, it is well to remember that all so-called factors of safety are based on assumptions that are generally unsupported by adequate reliable experimental data; and this would seem to be very pertinent to the question of the safety of higher and still higher dams, designed in accordance with accepted theories. The design of all dams is at present, and, for some time, must remain largely in the field of empirics, and any too radical a departure from experience is fraught with more or less danger. One safeguard that the writer would suggest is provision for drawing down the reservoir wherever at all practical, even at large expense.

Probably the majority of gravity masonry dams fail by sliding upon, or beneath, their bases. Strictly analyzed, several factors are involved in such failures of which little is known. As to frictional resistance to sliding upon the base, it is generally conceded that this may be from 55 to 70% of the pressure upon the base, or perhaps a little more in exceptional cases. This opinion seems to be fairly general. On the other hand, what can be said of bonding and of shear? It is well known that some existing dams are not safe against sliding as determined by the theory of frictional resistance alone, with 70% as the upper limit, yet few have expressed an opinion as to the probability of extensive bonding, and as to what reliance may be placed upon it. Mr. Wiley mentions two instances in which more or less bonding was demonstrated, but he fails to state whether or not it was general and expresses no opinion as to its reliability in the general case.

During the construction of the Wilson Dam the writer had occasion to build a pier which, later, had to be removed. It was founded upon horizontally bedded sound limestone of a highly siliceous character that was entirely free from cracks, and was comparatively smooth. The surface was thoroughly flaked and nicked by hammering with 4-point heavy drill-bits, and was made perfectly clean by repeated washing with high-pressure jets of air and water. A good coat of neat cement grout was then applied and broomed in and the pier was constructed of a good quality of 1:2:4 concrete. The writer was very anxious to know to what extent bonding had been effected, but was not much surprised to learn that only 4% of the area of the base had bonded with the rock surface. This too took place directly under the point from which concrete was dropped into the forms in the initial stage of construction, and there seemed no other reason why it should have bonded at this point rather than elsewhere. This point was not at the center of the pier, and the surface there was apparently no rougher than elsewhere.

It is the writer's theory that upon smooth horizontally bedded rock initial bonding takes place quite generally, if the rock is perfectly clean and sound, but that in the process of crystallization the concrete pulls away before adequate strength is developed. However, this is only a theory, although in the case of the pier mentioned he thought he could detect slight evidence that this had happened. The shape of the foundation may have been a factor in the result. The base of the pier was only 4 ft. wide and 24 ft. long.

Advocates of the theory of extensive bonding sometimes base their opinion upon results obtained in brick and stone structures. In this, they overlook

the fact that, in such a case, the mortar generally constitutes a very thin sheet and lacks the necessary cohesive strength to pull away, and that cracks form in the sheet instead. This might possibly explain the bonding observed by Mr. Wiley in the overturned sections of the St. Francis Dam. Weakness in the planes of lamination or the joint planes of the mica schist may have yielded to the cohesive strength of the concrete. However, it is easy to believe that if the foundation presents a sufficient number of prominent projections, such as would generally be the case if the stratification was upon edge, or dipped strongly, effective bonding may be obtained to a very considerable extent, with care in cleaning and grouting.

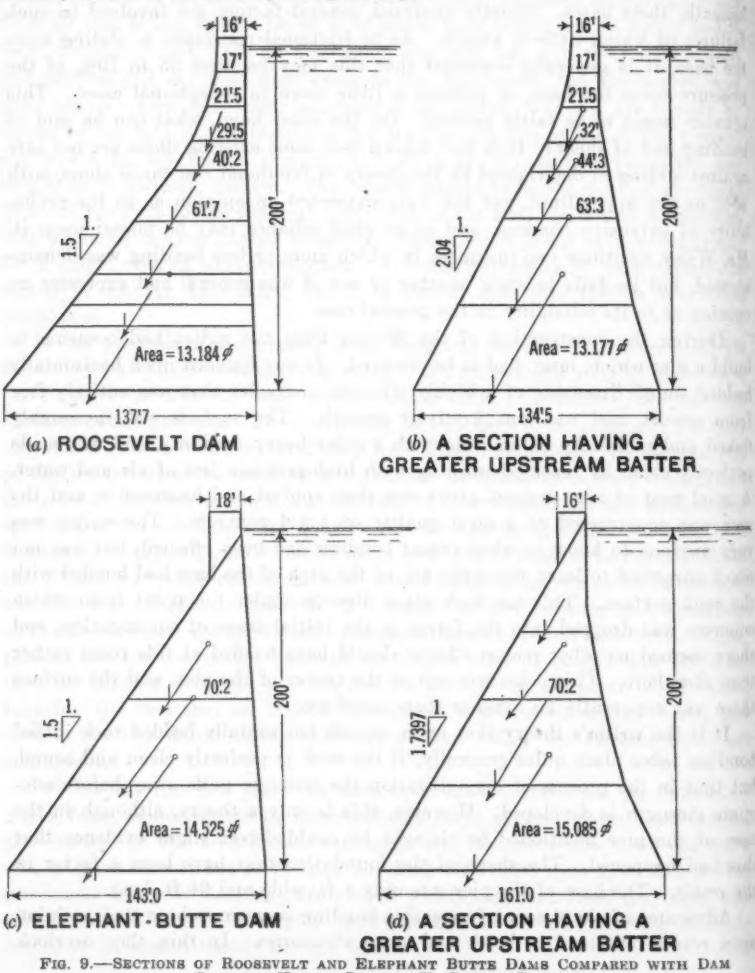

FIG. 9.—SECTIONS OF ROOSEVELT AND ELEPHANT BUTTE DAMS COMPARED WITH DAM SECTIONS HAVING GREATER UP-STREAM BATTER.

Lacking evidence as to the extent upon which effective bonding may be depended, it is necessary to rely upon frictional resistance. For this, greater pressure on the base is demanded, and the writer has often wondered why dam designers have not made greater use of up-stream batter in the case of gravity sections. Fig. 9 and Table 2 are presented to show that greater up-stream batter is not inconsistent with cantilever resistance and minimum sections. Fig. 9 (*a*) and Fig. 9 (*c*) represent sections of the Roosevelt and the Elephant Butte Dams[65] from their crests to a water depth of 200 ft. Since both these dams are much higher than 200 ft., the diagrams shown may not fairly represent stability at their bases, but since they are fairly typical of 200-ft. dam sections as usually battered, they are used.

TABLE 2.—Comparative Dam Sections Showing the Advantages of Up-Stream Batter.

(See Fig. 9.)

| Item. | Roosevelt Dam: Section above the 200-ft. water depth. (Fig. 9 (*a*)). | Section having an up-stream batter greater than Roosevelt Dam (Fig. 9 (*b*)), but having the same sectional area. | Elephant Butte Dam: Section above the 200-ft. water depth. (Fig. 9 (*c*)). | Section having an up-stream batter greater than Elephant Butte Dam (see Fig. 9 (*d*)), and an area only 4% larger. |
|---|---|---|---|---|
| Weight of masonry, in pounds per cubic foot | 155 | 155 | 145 (assumed) | 145 (assumed) |
| Uplift, in any horizontal plane (in percentage): | | | | |
| At the heel | 0 | 0 | 50 | 50 |
| At the toe | 0 | 0 | 0 | 0 |
| Sectional area, in square feet | ..... | ..... | 14 525 | 15 085 |
| Factor of safety against overturning | 2.260 | 2.263 | 1.93 | 2.32 |
| Ratio of weight to horizontal pressure | 1.680 | 1.839 | 1.378 | 1.626 |

It will be noted from Table 2 that Fig. 9 (*b*) has the same sectional area as Fig. 9 (*a*), but that it has a greater up-stream batter; yet it develops a 15.9% greater resistance to sliding and has a slightly better cantilever resistance. Fig. 9 (*d*) having a sectional area only 4% larger than that of Fig. 9 (*c*), develops a 24.8% greater resistance to sliding, and 19.5% greater cantilever resistance. The resultant of pressures on the base of Fig. 9 (*c*) falls slightly outside the middle third, under the weight of concrete assumed, whereas in the base of Fig. 9 (*d*) it falls within the middle third; hence, the difference in sectional areas.

In the face of this apparent advantage of greater up-stream batter, why is it not more generally adopted? Is the present custom a relic of the past, when such dams were generally constructed of rubble masonry, and shearing resistance was more questionable, or do designers really fear the development of cracks in the battered up-stream face? To the writer it would seem much morely likely that cracks would develop in the toe of the Roosevelt

[65] As taken from "Construction of Masonry Dams," by Chester W. Smith, pp. 247 and 253.

section. If cracks are not feared, then what is the real objection to such a section?

Hydrostatic uplift is another question about which there seems to be no unanimity of opinion. All agree that there must be more or less uplift, but they differ as to its probable amount. Naturally this will vary greatly on different foundations, and it is not expected that this feature of design could be standardized; nor would it be desirable. Data on uplift are gradually being accumulated from measurements on existing dams, and within a few years something may be known about the subject. In the meantime, however, would it not be well to assume that with the best of foundations the uplift may be as much as full reservoir pressure at the heel and tail-water pressure at the toe, acting upon 50% of the base? In the writer's opinion this gives a dam section that is none too conservative. This, of course, is assuming that effective drainage is not provided for, or cannot be relied upon.

Mr. Wiley has touched upon leakage, or seepage along "cold joints". Leakage, or seepage, is decidedly objectionable in any dam, and is, of course, especially objectionable in thin arched dams, or others composed of comparatively thin sections. All concrete workers appreciate the difficulty of treating a cold joint so as to make it water-tight, and they know that, even with the utmost care in picking, cleaning, and grouting, some joints may be expected to seep, if not leak. One remedy, of course, is to have no cold joints. It is the writer's experience that, if the succeeding lift be cast within 24 hours of stopping, only reasonable care in cleaning, wetting, and grouting is necessary to secure water-tight joints in a moderately thick section. This, however, is not always practical, and for reasons touched upon by Mr. Henny, may not be desirable. In a recently built thin arched dam plate-steel water-stops set into the superimposed lifts were used with good results, and the writer knows no good reason why the practice should not become general—particularly in thin sections. The use of these water-stops, however, should not excuse careless cleaning and grouting.

Mr. Henny expresses a suspicion that cracks through construction blocks more or less parallel to the water face may sometimes form. The writer fears that they generally do form in dams of heavy section. The construction blocks of Wilson Dam were alternately 38 ft. and 54 ft. long on the axis of the dam, and near the base were from 75 to 90 ft. in the other dimension. The writer in many cases observed that when the upper lift had been cast about ten days or two weeks, fine cracks would appear on each side of the lift somewhere near its mid-length. These cracks could be traced part of the way across the block, from each side toward the crack in the opposite side, and the writer feels reasonably certain that some at least extended entirely through the lift. The concrete was perhaps the best the writer ever saw used in a dam. If these cracks form in blocks of this size what can be expected of blocks of a high gravity dam?

Mr. Henny suggests as a remedy that the thickness of successive blocks be limited to 4 or 4½ ft. and slower construction, with the view of holding the temperature down. It has occurred to the writer that lower lifts would be of advantage for a different reason—not to prevent cracks, but with the hope

that cracks in the superimposed lifts would break joints, and would not lie in the same vertical plane. Thinner lifts would favor lower temperatures, but they would also favor more rapid cooling and drying, which would tend to produce cracks. Besides, in most cases, thin lifts would be most vexatious and costly in their effect upon speed of construction, and the greater number of "cold joints". When, in the construction of the Wilson Dam, the 12-ft. lifts were reduced to 6 ft., progress was reduced by at least 25%, and the cost of placing raised to a greater extent, although the great length of the dam was especially favorable to the use of thin lifts. In this case, since forms were handled by traveling cranes in large sections (an entire side at a time), it was easy to construct and hold the forms for a 12-ft. lift. The reduction of lifts to 6 ft., therefore, cost considerable money, and, in this case, was probably of doubtful advantage.

Shrinkage and cracking are troublesome factors to concrete designers, and it occurs to the writer that the cement manufacturer and his chemists could probably contribute much to remedy this condition. Early cracks and planes of weakness seem to form much more readily in concrete made of certain cements than in that made of other brands. Aging of the cement of course improves this condition, but it is probable that the chemist could find means more effective. The use of pre-cooled mixing water during warm weather, as suggested by Mr. Henny, would certainly contribute to the desired result.

As to temperature stresses in well-seasoned concrete, do engineers really know much about these? The coefficients of expansion of different aggregates are given by some, as follows: Limestone, 0.00000251; granite, 0.00000868; and quartz, 0.0000101. These show a wide variation. Therefore, is it not certain that concretes made of different aggregates would show almost an equal variation in coefficients of expansion, not to mention concretes of different densities made of the same aggregates?

Mr. Henny states that,

"Concrete with a known strength of 3 000, 4 000, and even 5 000 lb. per sq. in. in 28 days is now readily secured, and there seems to be no reason why concrete in the base of a dam could not be safely subjected to compressive stresses of 1 000 lb. per sq. in., or even more (such as would obtain in a dam about 630 ft. in height), provided a source of satisfactory aggregate is at hand, and a proper mix is used."

The statement as worded is carefully guarded, but it may be well to emphasize its limitations by introducing a few more definite provisions: First, that the maximum stresses can be known within a reasonable degree of approximation and that they may not exceed this limit, temperature stresses being considered; second, that such stresses be not used in thin sections subjected to water-soaking, and to wide temperature changes; third, that designers do not deceive themselves as to the feasibility of securing the early strengths specified; and, fourth, that reliance can be placed on the permanent quality of the concrete. All these may be implied in the statement, but its limitations cannot be too strongly emphasized. However, taken as it stands, if the base of a dam of gravity section is meant, it can do no harm for the reason that, at present, economics would bar the construction of a 630-ft. dam except in narrow

canyons having sound abutments, where its resistance to punching shear would be a very large factor in its stability.

As to the manufacturing of concrete and present knowledge of it, have engineers really made as much progress within the past few years as they sometimes imagine? In the writer's opinion, some of the more conservative engineers are entirely too confident of securing a specified strength. Density and water-tightness are not synonymous with strength, although they are important elements in the durability of concrete, which fact is sometimes overlooked.

Within the last several years the writer has had reason to make an occasional visit to a rather high dam that was under construction, in which high stresses were expected and for which claims of especially high-grade concrete were being made. Undoubtedly those who made such claims believed them to be true, but it was the writer's observation, confirmed by several visits, that the control exercised was entirely too lax to expect such results, and that in parts of the structure, at least, they most certainly were not secured. Some of the aggregate was too dirty for use in any structure; some of the batches that went out, appeared to be practically all mortar; occasionally, batches went out that were sloppier than the writer ever approved in the most reckless period of concrete history; and when the dam neared completion places could be pointed out where excess water was used.

In another case, the writer is told that a certain high dam which is known to have been built under rigid specifications, based upon Professor Abrams' discoveries as to strength, fineness modulus, and slump, leaks and seeps to an unusual extent.

With these experiences and others equally convincing, it is best not to be deceived in the idea that it is easy to secure a concrete of predetermined strength and density. It is not easy, and with the utmost care the results are sometimes disappointing.

Therefore, the writer advises caution in the matter of increasing the working stresses in high dams—particularly in high, thin dams. Twenty-five years hence something may be known about concrete. At present, there are very many things that engineers do not know.

A. J. Wiley, M. Am. Soc. C. E. (by letter).—Professor Switzer begins his discussion by citing three points in the main paper with which he cannot agree. The writer accepts these points as fair presentations of the claims made in his paper.

With reference to the first point Professor Switzer takes the case of a vertical slice of a dam, 1 ft. thick at the up-stream face and converging on radial planes, with full water pressure upon the up-stream face. The length of base is computed to bring the resultant, with reservoir full, at the third point for a dam, 1 ft. thick at the face, with parallel sides. He then shows that in the slice with converging radii and with the same water pressure there will be tension in the up-stream face, a conclusion for which neither argument nor calculation is needed.

Professor Switzer then calculates the deflection of the cantilever with reservoir full and concludes that it is so small that "the convergence of the radii would not close up any contraction joints such as are used ordinarily between blocks of the dam", and that, "therefore, no arch action can develop".

It would seem from the quotation that Professor Switzer believes that the contraction joints in a dam are built like those in a sidewalk, or pavement, with an actual opening filled with some plastic substance to provide for expansion. Nothing could be farther from the fact which is, of course, that concrete is tamped direct against concrete, with not even the thickness of a sheet of paper in the joint, and with the adjacent faces interlocking by offsets in one face into which the concrete of the other is poured.

Professor Switzer then states that arch action can be expected only when the contraction joints are grouted at times of low temperature, or when the arch has a comparatively short radius, and concludes that "arched action in a curved gravity dam cannot be expected."

The writer disagrees radically with both the statements and the conclusion of Professor Switzer as cited in the preceding paragraph. He is aware that there is much support for Professor Switzer's attitude in recent engineering literature, but he thinks that much of it is from prejudiced sources. In a few actual cases perhaps a very thin arched dam contracted due to the shrinkage of concrete, because it set in air, or because it was so thin that it was fully subject to seasonal or even daily temperature changes and contracted with the cold.

There may be a case in which a thicker dam has shrunk while the concrete was setting, due to a combination of very rapid pouring, an excessive use of water in the mix, or a poorly graded and unwashed aggregate.

In the vast majority of arched gravity dams there is more effective arch action than in the thinner dams which depend for stability principally upon arch action. The more effective arch action in thick arched gravity dams comes from the fact that any mass of concrete setting in air has an exterior coat which shrinks in setting because of the lack of moisture necessary for complete hydration. The interior, protected by this outer skin from evaporation, remains moist for a longer period so that hydration of the coarser part of the cement and consequent expansion of the interior mass continues long after this action is suspended on the faces.

This dried out and contracted skin, which is inert so far as arch action is concerned, is a much larger proportion of a thin arch dam than of the thick arched gravity dam so that a larger proportion of the latter is effective as an arch.

From the nature of the situation, inspection of the contraction joints in a thick dam is confined to the vicinity of the faces of the dam, and to surfaces of galleries in the dam, either of which is a case of setting in air and is apt to show cracks due to the shrinkage which follows from this condition.

There is much evidence in the many thick arched gravity dams to show that the opening of the expansion joints extends only from 10 to 20 ft. into

the dam, beyond which distance the dam is practically a monolith. This is proved by the absence of leaks from the contraction joints at the down-stream face; in the case of the Mulholland Dam it was shown by pressure tests.

Professor Switzer also dissents from the writer's claim that there is no uplift due to water under-pressure in the voids of the concrete. There seems to be some difference of opinion as Mr. Jakobsen and Mr. Floris have also dissented from the writer's views on this subject.

To clarify the matter it will be assumed that in some way all the voids in the concrete eventually become filled with water and that the water in the voids is under full reservoir pressure at the up-stream face, gradually reducing to tail-water pressure at the down-stream face. On a vertical column of unit cross-section at the up-stream face, assume the concrete to have a proportion of voids represented by $p$. In each unit of height in the column of unit area the sum of the volume of the voids will be $p$. It will be assumed that the voids are cubes and that they are uniformly spaced both vertically and horizontally, with $n$ voids per lin. ft. There would be $n^3$ voids per cu. ft.; the volume of a single void would be $\frac{p}{n^3}$; its side or height would be $\left(\frac{p}{n^3}\right)^{\frac{1}{3}}$; its area would be $\left(\frac{p}{n^3}\right)^{\frac{2}{3}}$; and the area of all the voids in a single layer would be $n^2\left(\frac{p}{n^3}\right)^{\frac{2}{3}}$.

Assume that at any given point, $H$ ft. below the reservoir surface, the dam is cut by an imaginary plane passing through the bottom of a layer of voids. In this set of voids the upward pressure is:

$$U = 62.5\left[\left(H - \left(\frac{p}{n^3}\right)^{\frac{1}{3}}\right] n^2\left(\frac{p}{n^3}\right)^{\frac{2}{3}} = 62.5\, H\, n^2\left(\frac{p}{n^3}\right)^{\frac{2}{3}} - 62.5\left(\frac{p}{n^3}\right)^{\frac{1}{3}} n^2\left(\frac{p}{n^3}\right)^{\frac{2}{3}} \quad \ldots\ldots(7)$$

In the next set of voids $\frac{1}{n}$ above the cutting plane, the downward pressure is:

$$D = 62.5\left(H - \frac{1}{n}\right) n^2\left(\frac{p}{n^3}\right)^{\frac{2}{3}} = 62.5\, H\, n^2\left(\frac{p}{n^3}\right)^{\frac{2}{3}} - 62.5\, n\left(\frac{p}{n^3}\right)^{\frac{2}{3}} \quad \ldots(8)$$

The uplift from water under pressure in the voids of the column of unit area at the up-stream face is the excess of the upward pressure over the downward pressure at the imaginary plane, or,

$$U - D = 62.5\, n\left(\frac{p}{n^3}\right)^{\frac{2}{3}}\left[1 - \left(\frac{p}{n^3}\right)^{\frac{1}{3}}\right] \quad \ldots\ldots(9)$$

If $p = 0.06$ and $n = 20$, $U - D = 1\,250\ (0.0000075)^{\frac{2}{3}} \times (1 - 20)\ (0.0000075)^{\frac{1}{3}}$, or 0.2915 lb., which is the uplift per square foot due to water pressure in the voids. This is a constant for all heights of the dam and is seen to be negligible; but it is based upon the assumption of homogeneity in the concrete and would not apply to porous layers or any other departure from uniformity.

It appears from this that water pressure against the up-stream face does not affect the condition of stress in the concrete, but the assumption that voids are filled with water would add, for 6% of voids, 3.75 lb. per cu. ft. to the weight of the concrete. The net result of water pressure in the voids is to increase rather than to decrease the stability of a gravity type of concrete dam.

Mr. Noetzli expresses the opinion that contraction cracks parallel to the axis are likely to form in massive concrete gravity dams, and he proposes to provide for them by joints parallel to the down-stream face. The writer believes that there is no evidence of such cracks in any dam except in the open galleries where they may be purely local and due to shrinkage from setting in air. The writer recalls no indication of such cracks as those noted in Fig. 5. This diagram shows a crack in the large slab which broke from the down-stream face for some distance up from the base. The writer examined this slab very critically in the field only a few days after the failure for the purpose of finding if there was any line of demarcation between the slab and the dam from which it broke. There was positively none, and the plane of fracture was perfectly new and fresh. It was exactly such a fracture as might have occurred in a dam which was so highly stressed as a vertical cantilever as to be on the point of overturning about its down-stream toe.

There was no evidence visible to the writer of the extension of the plane of fracture above the slab to indicate it as a part of a system of cracks, as it is shown in Mr. Noetzli's section. Figs. 10 and 11 are from photographs of the St. Francis Dam taken under the direction of the State Commission of California only a few days after the failure. The photographs show very clearly all the evidence with respect to the alleged axial cracks in the dam, and close examination under high magnification convinces the writer that what Mr. Noetzli takes to be axial cracks are simply the boundaries of radial contraction cracks which had broken part way through the dam a considerable time before the failure. The writer recalls that there were areas of water-stained surface in the freshly broken concrete which were plainly due to old, nearly radial, contraction cracks which formed planes of weakness along which separation took place at the time of failure. The lines in the photograph which resemble cracks, the writer believes to be lines between the water-stained and the freshly broken concrete, and it will be observed that the most strongly marked lines are in a nearly horizontal direction ending at the up-stream face.

The writer feels that the evidence of the St. Francis Dam is certainly not convincing enough to warrant the introduction of inclined joints, with their new problems, in a concrete dam of the gravity type; nor does he think that the formation of cracks in the thin buttresses of multiple-arch and Ambursen dams, where shrinkage from setting in air occurs, is proof that similar shrinkage cracks are formed in the interior of massive gravity dams.

Mr. Noetzli's statements with respect to both the Owyhee Dam and the Boulder Canyon Dam are misleading. These structures are distinctly arched gravity dams in that they are of the same section as a straight gravity dam

of equal height, but are designed so as to divide the load between the cantilever and the arch, thus reducing the stresses in both systems.

Although the writer made the statement as quoted by Mr. Godfrey that in many, if not in most, straight gravity dams, no allowance has been made for uplift, he did not mean to imply his approval of this practice. He agrees with Mr. Godfrey that uplift is a force to be recognized in the design of the gravity type, masonry dams, but he contends that where suitable physical conditions in the shape of a reasonably narrow canyon are found, security against uplift forces can be provided by designing the dam as if there were no uplift and then building it as an arch, or as an arched gravity dam. He also agrees with Mr. Godfrey in not being willing to trust the safety of a straight gravity dam against uplift to the effectiveness of cut-offs or underdrainage, although they both increase the factor of safety, at least temporarily.

However, the writer does not at all agree with Mr. Godfrey in considering uplift as the principal source of failure in gravity type dams or that the allowance for uplift in the design would remove the possibility of failure. Moreover, there has never been a failure, so far as the writer is aware, of even a straight gravity dam designed without allowance for uplift, that could not be fully accounted for by defects, either in the construction or in the foundation, so serious that even the additional weight of a dam designed for uplift, although it might have delayed, would not have prevented, its ultimate failure.

The writer does not wish to be understood as advocating the design of gravity dams without provision for uplift either by additional weight in a straight dam or preferably by the use of the arched gravity type where the topography will permit, but in his opinion Mr. Godfrey neglects the most important requirement for a gravity type masonry dam, which is that it should be founded upon a bed-rock at least as strong and durable and as truly elastic as the masonry, in the sense that it should yield only elastically to the load imposed upon it by the dam. If the foundation yields inelastically, as any material except solid rock will, and thus does not recover from the compression when the load is removed, the material does not make a safe foundation.

The writer called attention to two important elements of strength gained from building gravity dams upon a hard solid rock foundation resulting from the union which takes place between the concrete and the bed-rock. This increases the resistance to sliding on the base and also eliminates uplift on all that part of the base where the concrete is in proper contact with the rock.

Mr. Godfrey compares porous concrete to a tube made of sponge with an outer skin which is elastic and impervious and attached to the body of the sponge. He then introduces water under pressure into the interior of the sponge-filled tube and finds, of course, that the resistance of the sponge to the expansion of the tube causes tension in its fibers. The principle stated by the writer was that no uplift was caused in a homogeneous mass of concrete by water under pressure in its pores. The writer did not claim that

FIG. 10.—VIEW OF ST. FRANCIS DAM, SHOWING CRACKS IN DAM STRUCTURE.

FIG. 11.—CLOSE-UP VIEW OF ST. FRANCIS DAM, SHOWING CRACKS.

if a vertical column of the concrete were enclosed in a water-tight tube there would be no tension in its walls if water under pressure were introduced into the tube; nor did he claim that there would be no horizontal tension in the concrete if it were attached to and made a part of the tube.

The writer cannot follow Mr. Godfrey's reasoning in citing as an example of uplift due to pressure in the pores of concrete, the case of a pier which he says was lifted by water pressure that entered a horizontal construction joint. He states that,

"The great weight of the pier * * * as well as what tensile strength the concrete possessed, were not sufficient to overcome the water pressure in the pores of this concrete, which, by Mr. Wiley's statement of the case, should be balanced and equal to zero."

It is not clear whether Mr. Godfrey thinks the uplift was due to water in the horizontal construction joint as he first indicates, or to water pressure in the pores of the solid concrete as he next asserts. Mr. Godfrey is also mistaken in attributing to the writer a statement that there would be no uplift in an open horizontal construction joint. The writer specifically pointed out "that every seam or void in a masonry dam is filled with water under pressure". In another instance he stated, "in the case of an open horizontal joint in the concrete * * * there is uplift for which allowance should be made in the designs * * *".

The writer also differs radically from Mr. Godfrey's views about the function and the value of grouting. In the first place it is not generally considered as preventing uplift, but acts like the cut-off wall in reducing it. Mr. Godfrey's conception of grouting seems to be that it consists of pouring mortar into an exposed and visible opening and his statements that: (1) "It would be practically impossible to grout up a crack"; (2) "it stands to reason that solid cement or colloidal cement will not penetrate thin crevices where water may freely go"; and (3) "some of these [rock seams] may be in a horizontal direction just beneath the base of a dam, and drilling would not disclose their presence. The cracks most difficult to grout are the horizontal ones, and these are the greatest menace to the stability of the dam". All these quotations would apply if the process of grouting were to be confined to pouring mortar or grout into foundation defects exposed by the excavation, but they are not relevant to the process of "pressure grouting" which consists in forcing a thin mixture of cement grout under high pressures through drill holes extending to considerable depths below the excavated foundation. This is the process universally used for high masonry dam foundations and although the writer does not claim that it removes the possibility of upward pressure entirely, it certainly reduces it by increasing the imperviousness of the rock at the heel of the dam.

Mr. Godfrey's criticism of drainage as a relief for uplift has some justification, the writer thinks, partly because of the possibility of the sealing of the drains by mineral deposits, and partly because of the danger of deterioration of the concrete or of the foundation by the short path which it offers for infiltrating water.

In Mr. Godfrey's concluding paragraph he accuses the writer of overlooking the necessity of providing "gigantic abutments" for arched dams where such dams are not built in "rock gorges", and thinks that if the cost of such abutments were added to the cost of the dam the economy of the arch dam would vanish.

An arched concrete dam is always built in a rock gorge and every part of the dam is always supposed to be on a solid rock foundation, the sides of the gorge constituting the massive abutments which Mr. Godfrey correctly claims to be necessary.

It seems to the writer that Mr. Godfrey has failed to give proper weight to the character of the foundation and that he assumes that defects in this vital part can be remedied by increasing the dimensions of the dam to provide for uplift. The writer believes that provision should be made for uplift either by arch action or by gravity, but he does not believe that either will make a safe dam on the kind of foundation that Mr. Godfrey discusses, one in which, for instance, "excessive soil pressure due to weight * * * would merely make the dam sink", or another in which "it would be impossible for rock, no matter how poor a quality, to issue in a blow-out. Only fluid or semi-fluid soil could be forced out from beneath the base of a dam".

It seems to the writer that no better description than these quotations could be given of an absolutely unsuitable material for the foundation of a high masonry dam, and that increasing the dimensions of a masonry dam on such a foundation would only delay the time of failure.

Mr. Jakobsen objects to the writer's reference to the Exchequer Dam as an arched gravity type because in the paper an arched gravity dam has been defined as one having a section capable of carrying the full load by its weight alone and having, in addition thereto, the resistance of the massive horizontal arch. Mr. Jakobsen insists upon analyzing the gravity action of an arched gravity dam by considering the water pressure as applied to its developed up-stream face while its weight is reduced by the convergence of the radii. The writer contends that instead of applying the water pressure to the developed length of the up-stream face of the arch it should be applied to its projection upon the plane of the chord, which would give the same total water load tending to slide or overturn the arched dam as there would be on the corresponding straight dam, while the volume of the arched dam of the same section would be considerably larger and its resistance to either sliding or overturning, without considering arch action, would be greater than for the straight dam. It is when the water pressure upon an element of the curved face is considered as resisted only by the converging radial slice of that element, that there appears to be more gravity resistance in the straight dam than in an arched dam of the same section. The analysis which Mr. Jakobsen uses to show that an arched gravity dam has less stability than a straight dam of the same section, assumes the arched dam to be converted into a straight dam of length equal to the developed up-stream face of the arch, the water pressure upon the straight face being resisted by a series of independent buttresses, each consisting of a unit section touching only at

the up-stream face and formed by converging radial planes. This would lead to what the writer considers the illogical conclusion that an arched gravity dam could with equal stability be expanded into a straight dam closing a valley as much wider than the actual valley as the curved face of the arch is longer than its chord. The writer's objection is that Mr. Jakobsen neglects the fact that the water pressure upon the face of an arched dam can be resolved into two components, one acting normal to the chord of the arc and resisted by sliding friction, or shear, and cantilever, or overturning moments, and the other acting parallel to the chord of the arch and causing only axial stresses in the dam.

Mr. Jakobsen contends that a transfer of some part of the load from the cantilever to the arch, even where there are no open joints extending entirely through the dam, may be prevented by a state of tension in the concrete due to shrinkage. The writer thinks it only reasonable to assume that where radial contraction joints have been provided—as is now almost universal practice—tension in the concrete between these joints may be considered as eliminated. The writer also thinks that in a relatively thick arched gravity dam shrinkage due either to temperature or to setting in air is confined to the concrete near the faces, while the interior, which is protected from temperature changes and from setting in air, tends to expand due to subsequent hydration of the coarser particles of the cement clinker, rather than to shrink in the process of setting.

Mr. Jakobsen intimates that there is an inconsistency between the writer's present position in this respect and the quotation to the effect that some years ago he considered all stresses in arched dams to be transmitted either in horizontal or vertical planes. The writer cannot see that these views are inconsistent.

The shrinkage crack in the Mulholland Dam mentioned by Mr. Jakobsen has been previously referred to by the writer as having been shown by test to be a superficial crack with a depth of less than 20 ft.

In explanation of Mr. Jakobsen's quotation from an article by the writer to the effect that if contraction joints are not provided in high concrete dams contraction cracks will form, the writer is still of the same opinion, except that later experience has convinced him that even where contraction joints have been provided in arched gravity dams the opening of the joints is superficial and probably not deeper than 20 ft.

Mr. Jakobsen questions the writer's statement that the pressure grouting of contraction joints would result only in filling them for a distance of 15 or 20 ft. from the surface, a conclusion which follows from the writer's previously discussed opinion that the opening of such joints does not extend more than this distance beyond the faces. The writer recognizes the fact that grout might be forced with an intensity sufficient to tear apart a closed contraction joint, and that in a case where, due to construction methods, open cracks are found to extend entirely through an arched dam, pressure grouting may be made to fill the entire joint. His conclusions regarding pressure grouting referred to ordinary practice.

Mr. Jakobsen asks for further explanation, illustrated by an example, of the writer's conclusion that if, as claimed by Mr. Jakobsen, the contraction joints should open so as to prevent arch action, the back pressure of the reservoir head upon the joints would compensate for the absence of arch action. The writer has already discussed the assumption previously made by Mr. Jakobsen that there might be a state of tension with no open crack, and has stated his conviction that it was untenable. In this case, too, there is the further condition that tension between open joints would not affect the result. In the case of an arched gravity dam, as the pressure in the reservoir is maintained, there must be some point where the joints are tight. The most unfavorable case for arch action would be that in which the joints were open all the way through, except for a tight seal at the down-stream face. The water pressure in the open joints normal to the faces of the radial sides of the segments between contraction joints can be resolved into components normal to and parallel to the center line of the segment. The normal components acting on the opposite sides of the segment will only cause compressive stresses in the segment. The parallel components will offset the water pressure on the projection of the converging sides of the segment, leaving as unbalanced water pressure only an area of each segment equal to its length at the down-stream face, so that each unit of the up-stream face exposed to unbalanced water pressure would be resisted by a gravity section with parallel sides, and would have the same stability as a straight gravity dam of the same section.

The writer wishes it understood that he is not advocating the construction of arched gravity dams with open radial contraction joints sealed at the down-stream face. He is simply attempting to show that, even if what he believes to be the untenable assumption—that an arched gravity dam cannot act as an arch because of open contraction joints—were correct, the dam would still have stability equal to that of a straight gravity dam of the same section because of back pressure in the open radial contraction joints.

Mr. Parsons questions whether arch action in an arched gravity dam having the same section as a straight gravity dam would offset the reduction in gravity action due to the convergence of the radii. The writer thinks he has shown in his reply to Mr. Jakobsen that, neglecting arch action, an arched gravity dam of the same section, does not have less resistance than a straight gravity dam when proper relation is maintained between the water pressure and the resistance of each dam. In fact, the arched gravity dam has the greater stability because the water pressure tending to cause sliding or overturning is the same in either case and the volume of the arched dam is considerably greater for the same vertical projection of the straight and arched dams.

The writer regrets that he has given Mr. Parsons and others who have discussed his paper the impression that he did not consider uplift with enough seriousness. This probably came from the fact that he was considering it with relation to one of his sub-headings, "Past Experience", and was trying to account for its general neglect in the past with apparent immunity from failure where other conditions were favorable. Uplift is one of the most

illusive of phenomena, and it may vary under different conditions in the same dam from 100% of the head on 100% of the area to zero. A gauge tapped into a uniform concrete near the up-stream face of a dam would probably show reservoir pressure, but, as the writer has attempted to show, there would be no uplift in the body of the concrete. Gauges or pressure pipes tapped into the bed-rock at the base of the dam which show pressure head do not necessarily indicate uplift on the base, but show potential pressure which may become active pressure, or uplift, in a defective bed-rock connection, just as the potential pressure shown by the gauge embedded in the body of the concrete may become active pressure in a non-homogenous condition of the concrete, such as its intersection by an open horizontal joint or by a layer of porous concrete. For this reason uplift should be provided against, and the writer thinks that in the deep and narrow valleys or gorges where high dams are usually built, this can be done most effectively by designing the dam so as to take advantage of its resistance both as a horizontal arch and as a gravity cantilever.

The writer agrees with Mr. Werner that it would not be advisable to design an arched gravity dam with open contraction joints sealed at the down-stream face. He does not wish to be understood as advocating such a design any more than Mr. Werner advocates the design of a curved dam with a convex down-stream face just because he called attention to the fact that under certain conditions it might be more stable than a straight dam of the same section.

The writer agrees with Mr. Werner's views as to non-existence of uplift in the voids of a homogeneous mass of concrete, and as to there being an unbalanced pressure between strata of unequal porosity. The writer does not agree with the view that this would lead to uplift at a point of perfect contact between the masonry and a rock that is free from seams and voids.

Mr. Jorgensen questions the writer's conclusion that "the contraction joints of an arched gravity dam do not prevent arch action", and states that most large arched gravity dams have open contraction joints in late winter. He refers especially to the Exchequer Dam and states that it has tension in the up-stream face and that it is physically impossible for it to receive any help from arch action in the winter because of open contraction joints.

The tension in the up-stream face of the Exchequer Dam, asserted by Mr. Jorgensen, only exists upon the assumptions that there is no arch action and that its volume should be calculated with converging radii while the water pressure is considered as acting upon the developed up-stream face instead of upon its projection upon the chord. This is an assumption which has been discussed by the writer in his reply to Mr. Jakobsen.

The absence of arch action in the Exchequer Dam asserted by Mr. Jorgensen on account of alleged open contraction joints has also been discussed by the writer in his reply to Mr. Jakobsen.

Mr. Creager's discussion of the possible inadequacy of the old theories of design when applied to the much higher dams contemplated for the future, is very timely and well considered. The writer believes that the greater

difficulty of providing an ample margin of safety against sliding and against tension as the height of dams is increased can be most efficiently provided by designs in which arch resistance is used in addition to gravity action.

Mr. Floris attempts to show upon the basis of the theory of Professor Fillunger, that the writer's claims with respect to the absence of uplift due to water pressure in the voids of a concrete dam are erroneous. His explanation of the theory is not entirely clear, nor is his statement of the writer's views entirely correct. His assertion that the writer limits uplift in a dam to horizontal seams in the rock foundation or to horizontal construction joints in the concrete is not consistent with the writer's claims which are that "there is no uplift in the body of a homogeneous mass of concrete, * * * nor in a perfect connection between the dam and the bed-rock, except that which may be due to a different degree of porosity in the concrete and the rock."

If the writer understands Mr. Floris correctly his interpretation of Professor Fillunger's theory is that there would be no uplift from pressure in the pores of a concrete dam unless there is greater resistance in one direction than in another, such as would result from one part being more porous than another, or from the difference in porosity of the cement paste and the aggregates. This is not essentially different from the writer's theory which is based entirely on the homogeneity of the mass of concrete. It is impossible from Mr. Floris' discussion to evaluate the amount of uplift which he claims would result from the difference in porosity of the various constituents of the concrete, but from the fact that the voids in the concrete would probably not exceed 6% of the volume and that it is only to the area of this small volume of voids that the difference in uplift (if there should be any) would apply, it seems evident that it would be a negligible amount.

The conclusion of Professor Fillunger from his experiments that dams exceeding 250 ft. in height cannot be safe, is startling, but fortunately Mr. Floris explains the apparent error by giving some details of the experiments from which it appears that cylinders made of alternate disks of tight and porous mortar were found to have practically no tensile strength in excess of that required to offset the unbalanced pressures due to water pressures of 8 to 10 atmospheres in the voids.

On the other hand, the tensile strength of homogenous samples of both porous and non-porous mortar was not affected by exposure to water pressures as great as 100 to 200 atmospheres. In the first case there was unbalanced water pressure in the pores due to alternate layers of porous and tight mortar, and in the other the pressure in the pores of the homogenous mortar was balanced so that no interior pressure affected the strength of the mortar.

So far as the writer is able to determine there is no conflict between his own conclusions and those of Professor Fillunger, except with respect to whether concrete as used in high dam construction can be considered as similar to the alternate layers of tight and porous mortar designed to give unbalanced pore pressures in Professor Fillunger's experiment first quoted, or whether it more nearly resembles the uniform mortar used in the last quoted test.

Mr. Wright gives the commonly accepted opinion of the resistance to sliding due to friction of a dam upon its base or upon seams in the rock beneath the base, as 55 to 70% of the weight. The writer believes that the most common cause of failure of straight gravity dams is sliding upon a more or less plastic seam in the rock a short distance below the base. In such cases the sliding coefficient may be very much less than the assumed minimum of 55%, but failure in that case results from a defective foundation against which no design might be able to provide.

Mr. Wright cites a case in which practically no bond was found between concrete and limestone bed-rock under a pier at the Wilson Dam. There is a theory that old concrete which has set in air forms a surface of calcium carbonate with which new concrete will not make a bond. Experience seems to confirm this theory, and Mr. Wright's discussion indicates that, in the matter of bonding with new concrete, limestone rock acts like old concrete. From the writer's experience he would conclude that with the usual care in cleaning and bonding to bed-rock, a perfect bond could be made with other than limestone bed-rock or, at least, with mica schist and sandstone.

D. C. Henny, M. Am. Soc. C. E. (by letter).—The writer has followed with intense interest the valuable discussion on high dams contributed by many experts. The attention which has thus been given to a difficult subject shows the papers grouped in the Symposium to have been opportune.

It is noted that Mr. Noetzli and Mr. Wright share the writer's opinion that there is strong probability that shrinkage cracks parallel to the water face will form in massive concrete of very high gravity dams, and that if formed they contain a serious element of danger, especially in straight gravity dams.

Mr. Noetzli defends the provision of well-drained contraction joints parallel to the dry slope contained in the specifications of the San Gabriel Dam, and although this dam may not be built, comments on this provision are none the less valuable.

Mr. Jakobsen, on the other hand, questions the wisdom of such joints in connection with a dam of unprecedented height, without, however, suggesting any substitute.

Contraction joints parallel to the down-stream slope have worked well in high buttresses of multiple-arch dams. It must be admitted, however, that these have the advantage of easy side drainage, obviating dependence on the thorough interior drainage of joints necessary in gravity dams. There is at least one precedent for such joints in an arch gravity dam, namely, the Sweetwater Dam, in Southern California, which as a result of being raised has a well-drained inclined joint in its enlarged structure. In that case the problem was complicated by the great difference in age between the old rubble masonry and the new concrete, but no difficulties appear to have resulted.

It is obvious that precautions may be advisable in dams of unprecedented height, which have not had to be used in lower structures and which are consequently an innovation. The caution advocated by Mr. Jakobsen in the use of innovations in high dam construction is very proper, provided it does not lead to the mere copying of precedent in lower structures.

Attention was called in the writer's paper to other means at hand to guard against cracking of massive concrete, namely, cooling the aggregates and mixing water or building the dam with large precast concrete blocks, to be placed in the dam after chemical heat has become fully dissipated. In summer construction, such blocks can also be pre-cooled. It is not certain that much, if any, serious extra cost is involved in the latter method, although its deviation from ordinary practice may lead contractors to bid on the safe side. At any rate, in the construction of unusually massive concrete masonry in dams, safety does demand that precautions are taken against the setting up of excessive thermal stresses in the mass and the formation of cracks which may completely change the distribution of stresses assumed in the design.

This is even more true when the tendency is considered, in the manufacture of cement, to increase the fineness of grinding, which leads to earlier development of strength and greater temperature rise. Careful study should be made of qualities of cement which will result in a reduction of temperature rise without sacrifice of ultimate strength. In that connection further research is desirable as to the effect of admixtures of siliceous substances like trass, which is understood to be freely used in Europe, and of pumicite, diatomaceous earth, and similar materials used in this country.

There is some evidence to show that heat generation would be reduced by the use of such admixtures without resulting in loss of strength. Experience with sand cement in the Arrowrock and Elephant Butte Dams, however, shows that admixtures may have an unexpected effect. In these two cases there has developed a tendency to surface disintegration. Evidently, a high degree of caution must be exercised in considering the use of admixtures on a wholesale scale in high dams.

Mr. Noetzli refers to the method of constructing the San Mateo or Crystal Springs Dam, near San Francisco, in blocks cast in place. The excellent result there obtained may be partly due to that cause, but even more important may have been the slow rate of construction progress and the relative coarse grinding of the cement, 90% passing through a 50-mesh sieve.[66]

The mere fact of casting concrete in blocks would probably not have saved the structure from cracks if it had been built with present-day speed and cement. In fact, one fine crack across the top was observed by the writer in 1906, which apparently passes indifferently through the planes separating blocks.

Mr. Wright questions the benefits which may be secured in dam construction by reducing the height of lifts as against the admitted disadvantage of more numerous construction joints. He admits that thinner lifts would favor lower temperature, but fears as a result of rapid cooling and drying, that through shrinkage cracks would form. There need be no question of rapid drying as it is becoming common practice to require concrete surfaces to be maintained moist for an extensive period, and especially the surfaces of lifts until covered by the succeeding lift. The average time of exposure is usually not very long

[66] *Engineering News-Record*, May 8, 1930. p. 768.

and even where there has been seasonal suspension of work, the writer has never observed cracks in the top surface of lifts where they were wet.

On the other hand he does not share the hope expressed by Mr. Wright that thin lifts would favor a break of joints in crack formation in successive lifts—the adherence between lifts and the tendency in concrete for cracks once formed to extend into the adjoining mass would prevent cracking in steps.

Vertical cracks approximately parallel to the water face and near the toe may introduce immediate danger in straight gravity dams. In arched dams they are strenuously to be avoided, but they do not introduce the same element of danger because they need not interfere with arch action.

Mr. Noetzli refers to the Owyhee and Boulder Canyon Dams as being of the single arch type. He is correct if it is understood that they are both designed on the assumption that loads are carried partly by arch and partly by cantilever. To insure such division of load it is necessary that especial attention be paid to available methods of minimizing thermal stresses.

Mr. Godfrey states that it is standard practice to neglect under-pressure in gravity dam design. This may have been true in the past, but since 1920, or even as far back as 1910, it is believed that this standard has changed. He quotes the writer as having given the impression that under-pressure is easily averted or avoided. This is hardly in harmony with the fact that uplift was given considerable prominence in the writer's paper, nor with the statement occurring therein that, "generous allowance for uplift in the design * * * are the only safeguards, * * *."

It may also be stated that the writer has deemed the subject of such far-reaching importance that he has urged experimental determination and research wherever practicable. The knowledge thus far gathered shows in two ways that assumptions concerning uplift in recent dam design have been ample. Uplift pressures as measured have been less in each case, where tested, than allowances made in the design; and investigation indicates that the assumption that such pressure is effective over 100% of the base, is very conservative. There is good reason to believe that with careful construction this percentage is less than 40, although this opinion should not lead to cutting down the present common assumption of 100% effective uplift area because it is in this matter of uplift that an ample factor of safety is most necessary.

Mr. Godfrey fears blocking of drains by freezing at the outlet and serious ineffectiveness of drains except in their immediate vicinity. The writer has never observed such effect of freezing and believes that, where drains discharge into open gutters in drainage galleries (as is now usually the case), no danger from freezing can exist.

Research as to uplift also indicates uniformly the reasonable effectiveness of properly spaced drains wherever points to measure uplift pressures have been installed. It is, however, of value to have present-day practice questioned as to effectiveness, because this should lead to closer attention to details. One requirement should be that drains must be straight and easily accessible for cleaning, and this detail is too often disregarded.

An interesting question raised by Mr. Godfrey is that of buoyancy in the case of concrete resting on a foundation below the level of back-water. It has been the writer's practice to consider full buoyancy. He believes, however, that no complete buoyancy due to tail-water can exist, because of the adherence of concrete to rock, or to concrete, and that its assumption in itself contains a considerable element of safety.

Mr. Godfrey's statement that tests for high dams have shown under-pressure of practically 100% back-water pressure after sufficient time has elapsed, is admitted where any pressure is found to exist. It is the area over which this pressure acts that remains uncertain.

The term "standard dam design" has been applied by Mr. Godfrey to arching gravity dams without consideration of the ability of the abutments to take arch thrust. The writer cannot agree to this and knows only of a few cases where this charge might hold true, the most notorious of which is the St. Francis Dam.

Mr. Jakobsen argues that "gravity dams should be designed as such, irrespective of arch action, and that arch dams should be designed as such irrespective of gravity action." Such conclusion appears to the writer to be ultra-conservative. There seems to be no reason why an analysis of stresses, such, for instance, as that by the trial-load method, taking into consideration temperature drop, tangential shear, and twist, should not be made the basis of design.

The complexity of the calculations might tend to create doubt as to the dependence to be placed on the result. Yet the highly satisfactory coincidence between calculated and estimated deflections in models establishes confidence in the reliability of the method. The uncertainty as to the elastic qualities of the concrete used and the seemingly unavoidable errors in some of the underlying assumptions make it necessary to limit stresses to a fraction of known strength.

Mr. Jakobsen's statement concerning the Crystal Springs Dam is welcomed. The dam has not been brought up to its maximum intended height and, therefore, has great excess strength. This statement should have been included in the original paper, but was unintentionally omitted.

As to cracks parallel to the water face in gravity dams, Mr. Jakobsen suggests that some cracks noted in galleries may extend only a short distance into the mass. This fact is difficult to determine, although where water oozes from such cracks the probability may well be that it extends for a considerable distance. One crack was observed a few years ago in the Elephant Butte Dam, in one of the cross galleries. Its position in this case robs this fact of serious significance, as it occurs about 10 ft. down stream from the main gallery and, consequently, far up stream from the toe, where such cracks would be most dangerous. It is significant that water slowly oozing from this crack indicates that the vertical drainage system is not 100% effective. The extent or depth of this crack is unknown.

In the Bull Run Dam a crack parallel to the water face has been observed in one of the cross galleries only 40 ft. from the toe. It is very fine and

extends across the gallery, but on neither side of the gallery does it reach the floor level; nor is there any visible crack in the floor. Careful scrutiny also failed to reveal any crack in the surface of the dam slope above its appearance in the gallery, and the strong probability is that the gallery crack is superficial in character and due to rapid air cooling and drying.

The fact that uplift under the base of dams may exist on planes having a down-stream pitch, and that its horizontal component constitutes an addition to the horizontal water loading, is a valuable contribution to the discussion from Mr. Parsons. The argument applies equally to uplift which may exist along construction joints within the body of a dam and indicates the desirability of giving construction joints in concrete an upward pitch in a down-stream direction.

This expedient as regards the down-stream half of the dam was adopted in the construction of the Bull Run Dam and is also applied to the gravity abutments of the Ariel Dam, on the Lewis River, in Washington. In both cases the more important object in mind was to avoid flat construction joints along which sliding might take place.

Mr. Jakobsen very properly calls atttention to the error which may be involved in the assumption that the vertical stress distribution across a horizontal plane in a concrete dam is linear. The 1908, the Ottley and Brightmore, as well as the Wilson and Gore, experiments with models, previously mentioned, indicate that this assumption, while it may be approximately correct at higher elevations, is in error near and at the base. In themselves, these experiments do not show that curved distribution of vertical stresses causes the maximum stress in a horizontal plane to exceed the maximum found with linear distribution. Nor do they necessarily indicate tension at the water face where compression was previously found; but they raise a serious doubt. This doubt is understood to be confirmed as a result of Mr. Jakobsen's application of the theory of least work to this problem.

These uncertainties may well have a bearing on the justifiability of arching a gravity dam in regard to which Mr. Werner and Mr. Hanna argue that additional expense is not warranted. To the writer it seems that, whether or not a curved gravity dam, after cooling, acts in all its parts as an arch dam when loaded, is not the only question. A relatively high dam will probably do so, in various parts of its height, as a result of cantilever deflection. The behavior will depend on numerous factors, especially temperature drop after arch closure or after pressure grouting of contraction joints. However, assuming that the dam does not initially act as an arch and that actual down-stream movement on its base or on higher planes must take place to put arch action into full play, and considering that it is only by sliding that gravity dams have failed, then it appears that, if the abutments are capable of taking arch thrust, a greater degree of safety must result from arching a gravity dam to a reasonably effective radius. This added margin of safety is, in the writer's opinion, worth considerable extra expense, at least until the forces due to uplift and those opposing sliding, as well as the interior stresses in the concrete, especially near the water face, can be estimated with greater certainty than at present.

The writer agrees with Mr. Jorgensen that there is no reason why an arch dam should not be built as high as any gravity dam on sites where it would fit—that is, where the nature of the rock abutments as well as the topographic conditions are suitable.

Mr. Creager argues that the tensile strength of concrete at the up-stream face of a gravity dam, as well as the shearing strength along sliding planes, if treated as margins of safety, are of far smaller relative value in a high than in a low dam. This argument is sound and should lead to the adoption of relatively safer sections for dams of increased height.

Mr. Hazen performed a real service in urging increased caution in the design of dams of unprecedented height.

J. G. TRIPP, M. AM. SOC. C. E. (by letter).—The construction of dams involves both skill and judgment to create in finality the thought of the designing engineer. Drawings and specifications when well done, attempt to delineate and determine, accurately, the masses to be opposed to the water.

The writer has confined his efforts to the technique of construction, and the technology of temporary structures for use in carrying out the designer's intention for the permanent dam. In constructing several dams he has observed a wide divergence of opinion between designers as to the effect of concrete cracking and uplift pressures. Each designer will set forth his best conclusion in the plans and specifications, which to the builder are often enlightening and sometimes contentious and disappointing. It is unfortunately true, in the writer's opinion, that many dams are cheapened for financial reasons beyond the limits of sound engineering. He has observed all too many such structures; however, he is also sensible to the fact that an engineer worthy of the name must "do with one dollar what any one can do with two."

Because of capital investment the tendency to-day in concrete dams is to design for strength at the sacrifice of impermeability, particularly in high dams where the cubic yardage is a progressive ratio function of the height. This is a mistake. The addition of pumice to produce lower permeability and overcome laitance deposits should be encouraged. It is claimed that the addition of pumice will reduce shrinkage which, of course, is much to be desired and investigations to prove this point should not be delayed.

Shrinkage cracking in the mass can be controlled to a great extent by attention to water-cement ratio, proper relationships in aggregates and their size, and by the methods and times of deposit in the forms. The addition of ample reinforcing steel, while costly, is effective. Properly embedded steel will last indefinitely. The shape of the pouring block and its dimensions and speed of construction are matters of controversy, and, even with such a splendid example as the Crystal Springs Dam, some substantial experimental work should be done in this field to determine the proper geometrical shapes before any decision as to good practice should be adopted.

The writer agrees with Mr. Noetzli that the theory of principal inclined stresses is valid. During the construction of several important dams, he has seen the actuality of dangerous cracking, which could have been controlled by the application of this theory in the design. The writer has seen cracks

develop rapidly both transversely and longitudinally during construction of large and small dams, in speedily as well as in slowly built work. He concludes, therefore, that speedy construction is not necessarily a concomitant cause for shrinkage cracking. Different cements and aggregates and water have marked effects, as do times of day in which the concrete is poured. Protection from sun and wind and sufficient curing water applied between initial and final setting minimizes "drying out" or primary shrinkage.

The writer's observations, working under the specifications of eminent authorities have led him to conclude that while many of the vagaries of construction may be blamed for partial failures, there is still a large amount of guessing as to what constitutes good practice, and not enough conclusive experimental data available as to what is good practice in the matter of concrete for either gravity or other types of dams. Among other things, he believes that to specify never less than a barrel of cement to the yard is good practice.

In the matter of foundation uplift, the writer believes that the structural geology of the sites answers grouting criticisms. Basalt will require a different treatment from an upturned sedimentary or a massive felsite. The writer has seen large masses of sedimentary rock disturbed by even low-pressure grouting, as suggested by Mr. Parsons. The writer agrees with other observers that uplift on foundations is a very potent destructive force and in all cases, under his observation, it has been considered in, or nullified by, the design. He does not agree, however, that proper drainage and either cement or asphalt grouting cannot control this force to a large extent.

Uplift between construction joints is easily controlled by horizontal copper water-stops, proper joint cleaning, and pouring of succeeding layers of concrete. It is certain that the contact between a thoroughly cleaned bed-rock and concrete is always tight and that uplift is of no possible consequence in that plane. The joints and seams below the dam are the danger spots. The shaping of the foundation assuredly has the effect desired by the designer, where the rock masses are suitable. Resultant forces can be directed to advantage by careful attention to this detail.

Finally, the construction of the dam must be manipulated and controlled with adequate and necessary plant. The fitting of plant to design conditions and specification limitations, should be understood by the directing engineer to the end that design and construction should work to the final result of safety and economy.

Without a better understanding of the hidden facts to be revealed by further investigation, it does not seem wise to predict either the type or the height of future dams.

# ADJUSTMENT OF TRANSIT AND STADIA TRAVERSES[1]

BY HOWARD S. RAPPLEYE,[2] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. LOWELL O. STEWART, PAUL H. UNDERWOOD, F. H. PETERS, H. PARRY, AND HOWARD S. RAPPLEYE

SYNOPSIS

This paper presents the problem of adjusting transit and stadia traverses by correcting the lengths only and sets forth an extremely simple method of applying the theory of least squares to the problem. The method suggested is so simple that it should be readily understood and utilized by any one at all familiar with plane surveys and their computation.

## THE PROBLEM

The transit and stadia method of traversing has come to be used very largely by the Civil Engineering Profession for preliminary, topographic, and for many other kinds of surveys. When traverses, run by the transit and stadia method, are closed upon the initial station, or when they are run between widely separated control points established by surveys of a higher order of accuracy, some form of adjustment is necessary to eliminate from the computed co-ordinates of the instrument stations the effect of errors of closure.

In both compass-and-chain and transit-and-tape surveys the angle and distance measures are similar enough in degree of accuracy to permit the use of a method of adjustment which places corrections on both angles and lengths. In traversing by the method of the transit and stadia, however, the angle measures far surpass the distance measures in the matter of accuracy. For this reason it seems desirable to adjust this type of traverse by a method which will place corrections on the lengths only.

With the modern transit, reading to single minutes, or even less, the angle measurements around a traverse can easily be made with such accuracy that

[1] Published in November, 1929, *Proceedings*.

[2] Assoc. Mathematician, Div. of Geodesy, U. S. Coast and Geodetic Survey, Washington, D. C.

the angle closure will be very small. The angular error can be eliminated by the occasional application of a correction of one in the last place. The discrepancies most likely will have occurred in angles measured between the shorter sides of the traverse, and corrections should preferably be applied to such angles. This method leaves the error of closure, or "failure", in latitude and departure, to be adjusted by placing corrections on the lengths alone and will not change the angles or bearings measured or arrived at by this arbitrary process of distribution.

The purpose of this paper is to set forth such a method of adjustment and to carry through a sample adjustment by way of illustration. The method is rigid, being a least squares adjustment,[3] but is presented in a more or less "rule-of-thumb" manner.

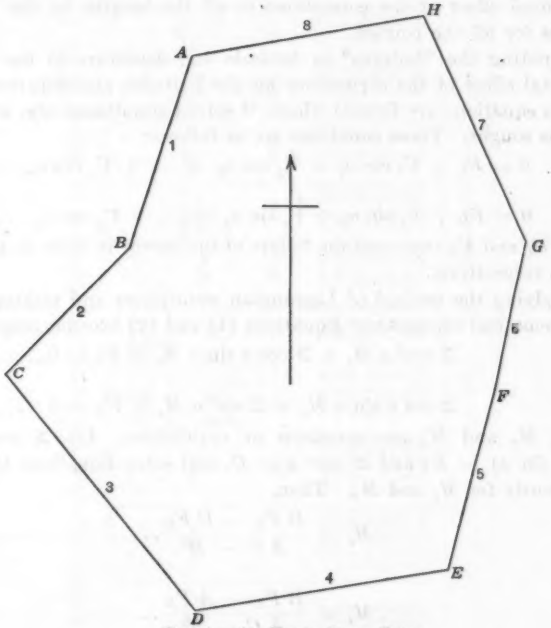

FIG. 1.—AN EIGHT-SIDED FIELD.

## METHOD OF ADJUSTMENT

The traverse which it is proposed to adjust is shown in Fig. 1. In Columns (1), (2), and (3) of Table 1 will be found the observed data for the traverse. Columns (4) and (5) contain the cosines and sines, respectively, for the bearings given in Column (2). The latitudes and departures given in Columns (6) and (7) are computed in the usual manner, and the column totals represent the failure of the survey to close in latitude and departure.

[3] The complete mathematical proof supporting this paper has been filed for reference in the Engineering Societies Library, 33 West 39th St., New York, N. Y.

Since the traverse is to be adjusted by placing the corrections on the lengths, the correction to Course 1 may be represented by the symbol, $V_1$, the correction to Course 2 by the symbol, $V_2$, and so on throughout the whole traverse.

If the bearings of the courses are represented by the symbols, $a_1$, $a_2$, $a_3$, etc., then, $V_1 \cos a_1$ will represent the effect of the correction to Course 1 on the latitude of Course 1. Similarly, the expression, $V_1 \sin a_1$, will represent the effect on the departure of Course 1 of the correction to Course 1. Similar expressions naturally follow for each of the other courses.

Then, $V_1 \cos a_1 + V_2 \cos a_2 + \ldots + V_n \cos a_n$ will represent the total effect of the corrections to all the lengths on the sum of the latitudes for all the courses. Similarly, $V_1 \sin a_1 + V_2 \sin a_2 + \ldots + V_n \sin a_n$ will represent the total effect of the corrections to all the lengths on the sum of the departures for all the courses.

By equating the "failures" in latitude and departure to the expressions for the total effect of the corrections on the latitudes and departures, respectively, two equations are formed which, if solved simultaneously, will give the corrections sought. These equations are as follows:

$$0 = F_L + V_1 \cos a_1 + V_2 \cos a_2 + \ldots + V_n \cos a_n \ldots\ldots\ldots (1)$$

and,

$$0 = F_D + V_1 \sin a_1 + V_2 \sin a_2 + \ldots + V_n \sin a_n \ldots\ldots\ldots (2)$$

in which, $F_L$ and $F_D$ represent the failure of the survey to close in latitude and departure, respectively.

By applying the method of Legrangian multipliers and making all necessary mathematical expansions,[3] Equations (1) and (2) become, respectively:

$$\Sigma \cos^2 a \, M_c + \Sigma \cos a \sin a \, M_s + F_L = 0 \ldots\ldots\ldots (3)$$

and,

$$\Sigma \cos a \sin a \, M_c + \Sigma \sin^2 a \, M_s + F_D = 0 \ldots\ldots\ldots (4)$$

in which, $M_c$ and $M_s$ are constants or multipliers. Let $\Sigma \cos^2 a = A$; $\Sigma (\cos a \sin a) = B$; and $\Sigma \sin^2 a = C$, and solve Equations (3) and (4) simultaneously for $M_c$ and $M_s$. Then,

$$M_c = \frac{B F_D - C F_L}{A C - B^2} \ldots\ldots\ldots (5)$$

and,

$$M_s = \frac{B F_L - A F_D}{A C - B^2} \ldots\ldots\ldots (6)$$

While the solution of this problem is a matter involving the Theory of Least Squares, in this particular case it is possible to make the solution of the two equations and the computation of the needed corrections to the observed lengths in a purely mechanical manner, as illustrated in Table 1.

The numerical values of the multipliers, $M_c$ and $M_s$, are found by substituting the values of $F_L$, $F_D$, $A$, $B$, and $C$, which are given as totals in Columns (6), (7), (8), (9), and (10), respectively. The desired corrections to the observed lengths are then represented by the expressions:

$$\left.\begin{aligned} V_1 &= M_c \cos a_1 + M_s \sin a_1 \\ V_2 &= M_c \cos a_2 + M_s \sin a_2 \\ V_n &= M_c \cos a_n + M_s \sin a_n \end{aligned}\right\} \ldots\ldots\ldots (7)$$

and their calculation is tabulated in Columns (11), (12), and (13) of Table 1. The adopted corrections, to the nearest tenth of a foot, are entered in Column (14). These are applied to the observed lengths to obtain the adjusted lengths in Column (15) and the adjusted latitudes and departures are computed as before, except that the adjusted lengths are used instead of the observed lengths.

If desired, the adjusted latitudes and departures may be computed by multiplying the corrections to the lengths in Column (14) by the cosines and sines, respectively. This will produce corrections which, when applied to the preliminary latitudes and departures, will give the adjusted values.

Special care must be taken throughout the entire calculation to see that the proper algebraic sign is used with each tabular entry, and in computing the values for $M_c$ and $M_s$ a rigid observance of all algebraic signs is necessary.

In cases in which it is desired to fit a traverse to two separated control points the fixed course of the line between the control points should be put into Table 1 as the closing side of the traverse. This course, then, will not be assigned a correction, and Columns (8) to (15), inclusive, will contain no entries on the line for the fixed course. The latitude and departure of the fixed course will be the same in the preliminary and adjusted tabulations.

Most of the calculation required in this method of adjustment (Columns (8) to (14), inclusive), can be performed with a slide-rule and the whole process is so extremely simple that it involves no mathematical "gymnastics" that are beyond the grasp of even the beginner in the art of surveying.

# DISCUSSION

LOWELL O. STEWART,[4] ASSOC. M. AM. SOC. C. E. (by letter).—The writer agrees with Mr. Rappleye that it is desirable to place the corrections for transit and stadia traverses in the lengths only; but he would add a few words in the way of caution lest one overlook some of the field conditions that may have an important effect on the results.

In the first place the example chosen seems to be at the very upper limit of accuracy in error of closure. Probably such accuracy would not be obtainable by ordinary methods with many of the transits in common use. As a rule the probable variation either way from the chosen reading is much more than 1 ft. at a distance of 1 000 ft.

Moreover, this variation is a sort of systematic error which seems to depend upon the individual. It has been found in many kinds of instrument work that an observer tends to "under-read" or to "over-read", on each observation. He rarely alternates. This seems to be true of stadia readings. The discrepancy will vary, approximately, with the distance because, as the length of sight increases, the intervals between the larger divisions would bear the same apparent relationships to one another as did the more minute divisions at the shorter distances. It would be wise, then, for an engineer who proposes to make an important stadia traverse to test his readings at various measured distances.

It is assumed, of course, that the stadia interval is known accurately. Many transits are functioning with home-made cross-hairs and the interval may or may not be the conventional "100", which is commonly used.

Atmospheric conditions have an important effect on stadia readings. On long sights the line of sight must pass near the ground where the refraction is uncertain and the readings are correspondingly unreliable. In the same way a line over a plowed field on a hot day would be differently affected from a line over a pasture, or over a body of water.

All the foregoing factors have an important bearing on any adjustment. In fact, their effect should be reckoned and applied before an adjustment is attempted. Unhappily, some of these factors are not always known with accuracy. In the latter cases one should be cautious about placing too much faith in a rigorous method of adjustment, such as the author has set forth in a thorough manner.

PAUL H. UNDERWOOD,[5] M. AM. SOC. C. E. (by letter).—The author has well assumed as a basis for the application of the method of least squares to this problem that the corrections applied to the latitudes and departures should not affect the azimuths or bearings of the lines of the traverse, and the method devised seems to be as simple as any that can be used for this purpose.

It has occurred to the writer, however, that an even better distribution of error, from the theoretical standpoint, is obtained by considering the corrections to vary as the lengths of the lines of the traverse. This may be done by introducing weights for the various courses. If these weights are considered to

[4] Asst. Prof., Civ. Eng., Iowa State Coll., Ames, Iowa.
[5] Prof. of Surveying, School of Civil Eng., Cornell Univ., Ithaca, N. Y.

vary inversely as the lengths, the solution can be carried out with no more labor than by Mr. Rappleye's method. The necessary changes in his equations are indicated as follows.

The latitude of a course is designated by $L$, and the departure by $D$. Furthermore, let $\Sigma\ (L \cos a) = A'$; $\Sigma\ (D \cos a) = B'$; and $\Sigma\ (D \sin a) = C'$.

With the weights varying inversely as the lengths of the courses the following equations may be derived to replace Equations (3) and (4), respectively:

$$A'\ M_c' + B'\ M_s' + F_L = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

and,

$$B'\ M_c' + C'\ M_s' + F_D = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

The solution of these equations for $M_c'$ and $M_s'$ gives:

$$M_c' = \frac{B'\ F_D - C'\ F_L}{A'\ C' - (B')^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

and,

$$M_s' = \frac{B'\ F_L - A'\ F_D}{A'\ C' - (B')^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

The desired corrections to the observed lengths are, therefore:

$$\left.\begin{aligned} V_1 &= M_c'\ L_1 + M_s'\ D_1 \\ V_2 &= M_c'\ L_2 + M_s'\ D_2 \\ V_n &= M_c'\ L_n + M_s'\ D_n \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

* As stated in the text, Columns (2) to (7), inclusive, of the author's Table 1, have been omitted in Table 2.

To illustrate this method, Table 2 shows the computations of the same traverse for which the calculations by the author's method were shown in Table 1. In the first eight columns, that is, to and including Column (7),

the tabulations are the same for the two methods, and are not repeated in Table 2. The quantities in Column (8), (9), and (10), Table 2, were computed by the use of the ordinary 10-in. slide-rule. It may be noted that all the signs of all the quantities in Columns (8) and (10) must necessarily be positive. The footings of the three columns are, respectively, $A'$, $B'$, and $C'$. Substitution in Equations (10) and (11) gives $-0.001104$ and $+0.001543$, respectively, as values of $M_c'$ and $M_s'$. By use of the slide-rule these values are multiplied by the latitudes and the departures, respectively, the calculated values being entered in Columns (11) and (12). The computations from that point are similar to those in Table 1.

A comparison of results by the two methods shows in this case no very great differences. One reason is that the courses do not vary markedly in length. A close examination reveals, as might be expected, that the corrections to the longer lines are in general larger and those to the lengths of the shorter lines are smaller by the writer's method than by that of the author. To get a comparison which would indicate more clearly the variation in the results by the two methods, the writer has taken another traverse in which there is a greater variation in the lengths of the courses. The resulting corrections are shown in Table 3.

TABLE 3.—Comparison of Closure Corrections for Field Containing Short and Long Sides.

| Course. | | Bearing. | Distance, in feet. | Correction to observed distance, in feet, by author's method. | Correction to observed distance, in feet, by writer's method. |
|---|---|---|---|---|---|
| No. | Station to station. | | | | |
| 1 | *K*–*L* | N. 23° 55′ E. | 528 | −0.3 | −0.2 |
| 2 | *L*–*M* | N. 38° 36′ W. | 540 | −2.1 | −1.7 |
| 3 | *M*–*N* | N. 50° 43′ E. | 671 | +0.7 | +0.7 |
| 4 | *N*–*O* | N. 78° 51′ E. | 375 | +1.6 | +0.9 |
| 5 | *O*–*P* | S. 20° 25′ E. | 868 | +1.8 | +2.3 |
| 6 | *P*–*Q* | S. 19° 38′ W. | 447 | +0.5 | +0.3 |
| 7 | *Q*–*K* | S. 79° 58′ W. | 937 | −1.6 | −2.3 |

It will be noted that the variations in the corrections are more apparent, the writer's method, based on weights, giving for the shorter courses smaller corrections and for the longer courses larger corrections. This is particularly noticeable when Courses Nos. 4 and 7 are compared, the method without weights leading to equal corrections for these two courses, while the method with weights gives a correction of +0.9 ft. for the shorter course and −2.3 ft. for the longer one. Since these two courses are nearly parallel, the variation is not due to other factors to any extent, but is due almost entirely to the weighting.

In conclusion, it may be said that, where all the courses are very nearly of the same length, there will be little variation in results by the two methods. Where there is considerable variation, the results will be noticeably different. Since the calculations are no more lengthy or difficult by the method with weights, and since this gives results which, on theoretical grounds, are superior, it would seem that this method is preferable.

F. H. PETERS,[6] M. AM. SOC. C. E. (by letter).—This paper deals with a problem that has been the subject of special investigation by the Topographical Survey of Canada, which has probably done more of this class of work than any other survey organization.

The rapid development of Canada's northland, immediately following the World War, hastened by the discovery of rich mines and a realization of the vast potential mineral wealth of the Pre-Cambrian shield, made a sudden demand on this Survey for topographical maps of hitherto unexplored country, and for surveys through this country to permit of the proper registration of all claims staked. The area to be surveyed is so vast that chained control surveys were out of the question, from considerations of speed as well as of cost. Hence, stadia traverses were run along the principal waterways for the dual purposes of providing a skeleton network of control surveys for the tying in of mineral claims and for ground control for the oblique aerial photographs from which the country was to be mapped.

In order to control these extensive stadia surveys, they were arranged in closed circuits wherever possible, and where this was not possible, astronomical observations for latitude and longitude were taken at intervals of 75 to 100 miles, and the stadia surveys were adjusted between observation points. The extent of these operations may be judged from the fact that in the six years immediately following the war, no less than 25 000 miles of stadia traverse were run by members of the Topographical Survey of Canada.

As regards the field work, it may be said that every precaution was taken to ensure freedom from gross errors both in directions and in distances, and many novel features were incorporated into the work with this end in view. Briefly, angle measurements, checked by frequent star observations for azimuth, are seldom more than 2′ or 3′ of arc in error, but the distances are subject to the inherent weakness of stadia measurements, so that as Mr. Rappleye rightly states, "the angle measures far surpass the distance measures in the matter of accuracy."

The field closing stipulated as being permissible between control points is $\frac{1}{400}$ of the surveyed distance, and these closing errors had to be distributed in some way. This led to an investigation of the method of adjustment best adapted to the conditions of the survey, yet not entailing too much office work. The tremendous amount of computations involved had a very important bearing on the method of adjustment to be adopted.

The investigation[3] was made by H. Parry, Mathematician of the Topographical Survey of Canada, who first examined the advantages and defects of the well-known Transit Rule[7] for balancing a closed survey. It was found that this rule produced appreciable changes in the accepted bearings of the courses, which were determined in the field with considerable accuracy. Consequently, an investigation was made to deduce a rule which would distribute the closing errors by correcting the lengths while leaving the bearings unchanged. This is exactly the same problem as that outlined by Mr. Rappleye, a least square

[6] Dept. of the Interior, Ottawa, Ont., Canada.

[7] "Theory and Practice of Surveying," by J. B. Johnson and L. S. Smith, Seventeenth Edition, 1912, pp. 235–236.

adjustment of which was made with exactly the same results as obtained by him.

After some consideration, however, it was decided that this least square adjustment, while possessing the advantage of leaving the bearings unchanged, was not exactly suited to the field conditions under which Canadian Government surveys are run. It is based on the assumption that all the errors in the lengths are of the accidental class, while actually the lengths are also affected by systematic or constant errors which it is not possible to eliminate entirely. A study of these systematic errors shows that a certain proportion may be accounted for by variation in the stadia constant of the instrument with different climatic conditions. This is due partly to an actual variation in the distance apart of the stadia threads and partly to the consistent bending of the rays of light, especially the lower ray, under certain atmospheric conditions. While engaged on work of this nature in Canada, field surveyors of the Topographical Survey, are instructed to determine the stadia constant of their instrument from time to time during the course of the survey and where necessary, corrections are applied to the stadia lengths. Glass diaphragms are found to give a less variable stadia constant than spider threads. It is not possible, however, to correct for the systematic errors due to refraction and other minor causes.

In addition to these considerations, the least square adjustment, as applied to the extensive traverses of the Topographical Survey of Canada, would entail an enormous amount of computation, and this led to the selection of the much simpler Transit Rule. Incidentally, it might be mentioned that the least square adjustment necessitates corrections to the lengths which, in general, are greater than those given by the Transit Rule. This, of course, is obvious, since the Transit Rule besides changing the lengths, also changes the bearings up to as much as 8′, while the least square adjustment confines all the corrections to the lengths.

It will be seen, therefore, that the least square adjustment deduced by the author would not suit the field conditions encountered by the Topographical Survey of Canada. It can readily be understood, however, that entirely different conditions of field and office work might make it very desirable to adopt a least square adjustment, and the Surveying Profession is indebted to Mr. Rappleye for bringing this particular solution to its notice.

H. PARRY,[8] ESQ. (by letter).—In 1921 the writer made a study of the methods of adjusting stadia traverses in order to distribute the closing errors of the extensive stadia traverses of the Topographical Survey of Canada. As the Transit Rule[9] is by far the most widely known and used rule for adjusting and balancing traverse surveys, the following investigation into the effect of this rule on the bearings of the traverse will be of interest in connection with Mr. Rappleye's paper.

[8] Mathematician, The Topographical Survey of Canada, Ottawa, Ont., Canada.

[9] "Theory and Practice of Surveying," by J. B. Johnson and L. S. Smith, Seventeenth Edition, 1912, pp. 235–236, and other standard books on surveying.

The rule has been formally expressed by Johnson and Smith, as follows:

"As the arithmetical sum of all the latitudes is to any one latitude, so is the whole error in latitude to the correction to the corresponding latitude, each correction being so applied as to diminish the whole error in each case. Proceed similarly with the departures."

To evaluate the effect on the bearing of any particular course, let:

$l$ = measured length of any particular course.
$a$ = bearing of course.
$L$ = arithmetical sum of the latitudes.
$D$ = arithmetical sum of the departures.
$F_L$ = error of closure in latitude.
$F_D$ = error of closure in departure.
$\lambda$ = correction to latitude of course considered.
$\mu$ = correction to departure of course considered.
$\delta a$ = change in bearing of course considered caused by a correction of $F_L$ to latitude and $F_D$ to departure.

Stated algebraically, the Transit Rule for any particular course gives, for latitude:

$$\frac{\lambda}{l \cos a} = \frac{F_L}{L} \quad \ldots\ldots\ldots\

closure is due entirely to errors in the lengths, then the correction in latitude to any individual course must be less than 1 in 400 of the latitude of that course and the correction in departure must be less than 1 in 400 of the departure of that course.

This is not strictly true in practice because, in a long traverse running almost due north and south, in which the arithmetical sum of the departures is very small compared with the extent of the survey, the error of closing in departure due solely to small errors of direction might be of the order of 1 in 400. A similar condition would hold for a traverse running almost due east and west. However, in the general case the errors in direction are of a smaller order than the errors in lengths.

In the extreme case, assuming that latitudes are too long by 1 in 400, and departures are short by 1 in 400, or *vice versa*,

$$\frac{F_L}{L} = \frac{F_D}{D} = \pm \frac{1}{400}$$

and, by Equation (17),

$$\delta a = \pm \frac{1}{2}\left(\frac{1}{400} + \frac{1}{400}\right) \sin 2a = \pm \frac{1}{400} \sin 2a$$

or, in minutes of arc:

$$\delta a = 8.5 \sin 2a \quad \text{.....(18)}$$

This is the change in bearing in the extreme case where latitudes and departures have their maximum allowable corrections of 1 in 400. It is a maximum for a course inclined at 45° to the meridian, in which case, $\delta a = \pm 8.5'$.

This introduction of errors into traverse bearings which have been accurately determined in the field is, then, the price that must be paid for ease and simplicity in the computations. It may be stated, however, that the work of the Topographical Survey of Canada is seldom affected by errors as large as 1 in 400, which are considered the maximum errors permitted without further investigation of the field work.

HOWARD S. RAPPLEYE, ASSOC. M. AM. SOC. C. E. (by letter).—The writer is indebted to Professor Underwood for a suggestion that is a decided improvement in the method of adjusting transit and stadia traverses, since his proposed method of weighting the various courses will undoubtedly result in better corrections. This method will also tend to remove the objection advanced in Professor Stewart's discussion.

The discussions by Mr. Peters and Mr. Parry present valuable information on the subject and serve to show that the treatment of the problem was checked, so to speak, before it was solved. It is superfluous, perhaps, to state that the writer had no knowledge of the work of the Canadian engineers in connection with this problem, until their discussions appeared.

The subject has been presented to the attention of the engineers of the country, much improved as a result of its discussion by others. It will be interesting to sit back and see what practical use is made of the method.

Paper No. 1768

# CONSTRUCTION OF THE JAMES RIVER BRIDGE PROJECT[1]

By R. C. Wilson,[2] Esq., and Herbert B. Pope,[3] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Wilson T. Ballard, William Willoughby, and R. C. Wilson and Herbert B. Pope

Synopsis

This paper describes the James River Bridge Project and the more important details of its construction. This being a toll bridge and involving a large outlay, it was necessary to make a careful investigation of probable expenditures to determine the soundness of the investment. The item of cost most difficult to predetermine was that of the concrete pile foundation work, due to the soft clay bottom of the James River.

A description is given of the general plan of operation of the work from a main base where materials were assembled. The methods of casting, handling, and driving the large concrete piles are outlined, as well as other details of the work in the field. Actual load tests on piles which did not drive to refusal furnished interesting data in regard to their carrying capacity.

The James River Bridge Project (Fig. 1) is an important link in the Atlantic Coastal Highway System and makes it possible for a motorist to reach Norfolk, Va., from the north and continue south without the former long detours or troublesome ferries. The project consists of three bridges, totaling 5⅞ miles in length, and about 11 miles of concrete roads built to give access to the bridges from existing highways. The largest of these bridges crosses the James River just beyond the city limits of Newport News, Va., and is about 4½ miles long. The other two bridges carry the highway over Chuckatuck Inlet and the Nansemond River, respectively. The traveler will now find a

[3] Supt. of Constr., Turner Constr. Co., New York, N. Y.

splendid concrete roadway leaving the Richmond Highway just west of Newport News, spanning the James River, Chuckatuck Inlet, the Nansemond River, and connecting with the State Highway leading to Norfolk.

*Early Studies.*—The preliminary work in connection with the project entailed first a very careful study on the part of the engineers as to the value of these bridges and connecting roads from an investment standpoint so that they might be certain that the revenue to be derived from tolls would represent a reasonable margin for profit beyond the cost of maintenance and the interest on the investment. A considerable amount of research work was necessary in order to determine even approximately the cost of the project. Surveys had to be made, borings and soundings had to be taken across the rivers on the proposed line of the bridges, and the cost of crossing private property with the right of way had to be ascertained.

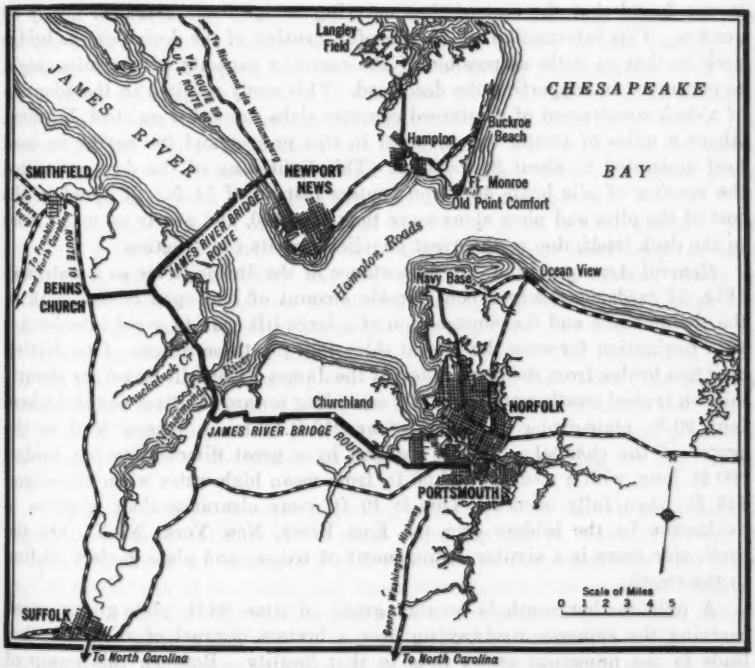

FIG. 1.—JAMES RIVER BRIDGE PROJECT WITH CONNECTIONS AND ENVIRONS.

It was assumed that pre-cast concrete piles would be used on this work, but as soon as the borings had been studied it was realized that some of these piles would have to be driven to unusual depths and that the resulting cost of the project might exceed the safe limit of investment. In order to obtain more accurate information, actual test piles similar to those finally used were cast and driven at intervals along the line of the James River Bridge. This work

indicated that many of the piles would have to be of great length, but that a pile-supported trestle was feasible and would cost less than any other type of permanent bridge structure.

The largest piles indicated by the test were 115 ft. long and 24 in. square, and weighed slightly more than 35 tons each. Many of them did not drive to refusal, although penetrating as much as 90 ft. of soft clay. Actual tests had to be resorted to for determining what load such piles might safely carry. When they came to rest an enormous grip developed between the soft clay and the great area of pile surface. Thus, where existing formulas based on penetration under hammer impact indicated a carrying capacity of only 18 to 20 tons, the piles actually supported a load of 90 tons without settlement. The maximum bridge loads that the piles will ever be called upon to support will be 42 tons each.

When the estimate of making and driving these great piles was completed, it was found that the cost of thus carrying bridge loads averaged nearly $9 per ton. This information led to a careful scrutiny of the design of the bridge deck so that as little as possible of the carrying capacity of the piles might be consumed in supporting the dead load. This study resulted in the adoption of a deck constructed of reinforced concrete slabs supported on steel I-beams. About 5 miles of trestle was involved in this project and the saving in dead load amounted to about 26 000 tons. This lightening of the deck permitted the spacing of pile bents 44 ft. on centers instead of 34 ft. It saved in the cost of the piles and piers alone more than $300 000, and nearly as much more in the deck itself, due to the great simplicity of its construction.

*General Arrangement.*—The importance of the James River as a waterway (Fig. 1) made necessary a considerable amount of long-span bridge work in the channel area and the construction of a large lift span to avoid interference with navigation for even the largest ships that ply these waters. One driving over this bridge from the north shore of the James River will travel for about ¾ mile on typical trestle work gradually ascending toward the river channel where four 90-ft. plate-girder spans and four 210-ft. through trusses lead to the center of the channel. This is spanned by a great direct-drive lift bridge, 300 ft. long, with a clearance of 50 ft. from mean high water when closed and 145 ft. when fully opened. This is 10 ft. more clearance than is given to navigation by the bridges over the East River, New York, N. Y. On the south side there is a similar arrangement of trusses and plate girders leading to the trestle.

A mile farther south is another group of nine 90-ft. plate-girder spans carrying the concrete roadway up over a branch channel of the river that leads to the numerous oyster beds in that locality. Between this group of plate-girder spans and the south shore of the river is a fine stretch of typical trestle work more than 2 miles in length—straight and almost level. The two smaller bridges have the same type of trestle work as that over the James River. In each case the channel is spanned by a double-leaf bascule of the rolling type, 110 ft. in length, which gives ample clearance to navigation on these less important rivers.

Between the north end of the James River Bridge and the main highway running from Richmond, Va., to Newport News (Fig. 1) is an elaborate

approach laid out around a plaza. At the south end of the same bridge for a distance of about a mile there was a difficult piece of roadway construction, through a swamp almost at tidal level. Here, the bottom was so soft that it had to be removed and sand pumped in from the river to form a suitable bed for the concrete roadway. About 8½ miles of concrete roads were constructed on the peninsula between the James and Chuckatuck, while between the Chuckatuck and the Nansemond about 1½ miles of concrete road had to be built, but these stretches are over higher land, where there was no trouble in finding proper foundation. Similar conditions exist to the south of Nansemond where about a mile of concrete roadway has been completed to connect with the existing highways leading to Portsmouth, Va., and Norfolk.

*Locating Bridge Lines.*—As part of the preliminary work on this project, extensive surveys were made. Base monuments had to be established by careful triangulation and permanent working points had to be set so that it would be possible to start construction at different locations along the line of the bridges without the probability of error of closure as each part of the work developed and approached the other. The initial triangulation work was done under the auspices of the U. S. Coast and Geodetic Survey which assigned engineers to establish the monuments designating the terminal points of the three bridges. No great problem was presented by the location of the roads, or even the two smaller bridges, and station points were established along the lines so that work could be started at any desired location.

The survey work on the James River was a more serious matter. The terminal points were nearly 24 000 ft. apart. Deep water intervened for most of the way and the visibility was apt to be poor. It was decided finally to erect pile-supported platforms at intervals along the line of the bridge and on these rigid bases to locate accurate transit points that would be used as reference marks in starting any section of the work. The instrument point in the center was located on a platform supported on four wood piles securely wrapped and stapled together. The working platform surrounding the instrument point and independent of it was also built on wood piles and permitted mooring of boats to the platforms without danger of moving the instrument point.

*Material Testing.*—A concrete testing laboratory with modern and complete equipment was established at the main operating base in Newport News. A screen analysis of the sand and gravel was made as these materials were being towed to the site of the work, and exact instructions were given at frequent intervals to the different mixing plants as to the proportions of sand, gravel, cement, and water which were to be used in the concrete for the different parts of the work. Specimen cylinders were made of the concrete actually being used each day and these were broken at 7, 14, and 28 days, so that there might be an exact control of the strengths of concrete specified without any waste of cement.

Other test cylinders, cured under various weather conditions, were broken at from 2 to 10 days, and the information thus gained as to the early strengths of concrete was used as guides in determining the safe time for removing the forms. This led to economy in form building by not having any of the center-

ing left in place for unnecessary lengths of time. A 1 : 1½ : 3 mix was used in the concrete piles and for all cap and pier work to Elevation + 5.0. All other concrete was designed for a 1 : 6 mix.

*Working Base.*—In the construction of this project the problem of first importance was the establishment of a main operating base. For this, certain qualifications were essential, such as:

1.—Deep-water wharfage.
2.—Rail connection.
3.—Electric power; fresh water supply.
4.—Harbor for refuge of floating equipment.
5.—Sufficient area for storage of materials, pile-casting, and storage yard, carpenter shops, offices, and room for fabrication and storage of reinforcement, and many other items.
6.—Reasonable accessibility to the different parts of such an extensive work.

A survey of available sites, fortunately revealed one that was ideal for all requirements. Accordingly, a lease was taken of the major part of one of the shipyards that had sprung into being during the World War. This property was situated within the city limits of Newport News and fronted for a distance of 700 ft. on Hampton Roads, with a wharfage of 1 700 ft. along a small boat harbor where floating equipment could be tied up. All this dockage was required because when the many craft had to seek shelter they were moored two and three deep along the bulkhead.

As shown in Fig. 2 the principal area was devoted to the casting and curing (30 days) of the 2 980 concrete piles. Thus, with the sections required for the fabrication of the reinforcement and the casting it was necessary to set aside for the pile yard a space, 1 100 ft. long and 125 ft. wide. This was served by a gantry crane which ran out over a slip on Hampton Roads where the piles were loaded on barges for transportation to the drivers.

Other principal parts of this yard were devoted to the storage of the heavy I-beams used in the deck construction, to saw-mills, to form-making yards, to storage of reinforcing steel and its fabrication, to space for building special barges, etc. Along the boat harbor, space was reserved for an emergency storage of sand and gravel. Fortunately, a marine railway was still in operation along the west side of this yard and hardly a week went by but one or another of the many pieces of floating equipment found its way to this railway for repairs.

*Pile-Casting and Handling.*—The pile-casting yard proper was constructed on a forest of 2 by 4-in. stakes driven into the ground. These stakes were spaced 18 in. apart, running lengthwise of a supporting 2 by 4-in. joist, and the joists themselves were spaced 15 in. apart. On top of the joists, ⅞-in. sheeting was laid for the width of the pile. The side forms for the pile were held at the bottom by a 2 by 4-in. cleat nailed to the joists; at the top they were braced and plumbed by a specially constructed removable cap member. Later, this was taken off to permit the side forms to spring apart and thus allow the lifting of the pile. The casting yard had a capacity of 140 piles, the lengths being adjusted by putting the end stoppers in the forms at any desired position.

Piles as long as 115 ft. could be poured on this platform. Longitudinal steel for the piles came in full lengths—117 ft. for the longest units.

The mixing plant for the casting yard consisted of two 1-yd. mixers which were fed from a large charging hopper holding approximately 400 yd. This hopper was loaded by means of a stiff-leg derrick which was located on the bulkhead in such a position that material could be charged directly into the hopper, either from the barges on which it arrived, or taken from a storage pile located under the swing of the boom. Aggregate entering the mixer was measured by batch hoppers and the water content was gauged accurately by means of an approved measuring tank. Cement was brought to the mixing plant from the cement house by a belt conveyor.

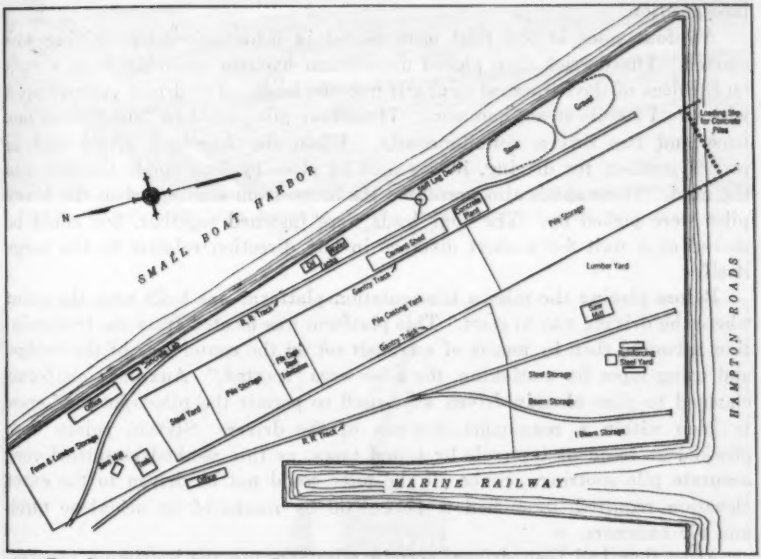

FIG. 2.—ARRANGEMENT OF OPERATING BASE, JAMES RIVER BRIDGE PROJECT, AT NEWPORT NEWS, VA.

After the piles had been poured for a period of approximately 7 days they were lifted from the forms by the gantry crane spanning the casting platform, using for this purpose, heavy T-bolts with washers, cast into the piles. Either three or four bolts were used, depending on the length of the pile. The loads on the T-bolts were balanced by blocks on an equalizing beam slung under the gantry. After lifting, the pile was carried to the curing yard, also under the crane (Fig. 3). There it was thoroughly inspected for cracks and flaws and was cured for a period of 21 days, or longer, by means of water jets. This yard had a capacity of approximately 500 piles. As piles were required they were picked up by the gantry crane which, running out past the bulkhead, was able to place them directly on a barge for transportation to the drivers.

*Pile-Driving.*—Shallow water near the shore on all three bridges necessitated the dredging of a channel 180 ft. wide and 6½ ft. deep along the line of the bridges from deep water to shore. These channels permitted the efficient use of the heavy floating equipment necessary for handling piles and other loads. The equipment used for placing the piles consisted of two large floating drivers. One was of the ordinary single-lead type; the other was called the "four-lead" driver (Fig. 4), and carried a derrick capable of handling the 115-ft. piles. This derrick picked up the pile from the transportation barge and placed it in the leads, using a rather complicated sling, with three or four points of suspension along the pile depending on its length, the loads being compensated so that no excessive strain was placed on it during the entire operation. When the pile was hanging directly plumbed, it was placed in the leads and lowered into position.

All four piles in one bent were placed in leads before the driving was started. The derrick then picked up a steam hammer assembly from a rack on the deck of the barge and swung it into the leads. The driver was equipped with two 7 500-lb. steam hammers. Thus, four piles could be "spotted" at one time and two driven simultaneously. When the four-lead driver was in proper position for driving, it was held in place by four spuds lowered into the mud. These spuds also prevented the barge from canting when the heavy piles were picked up. The four leads were fastened together, but could be moved as a unit for a short distance in any direction relative to the barge itself.

Before placing the piles a triangulation platform was built near the point where the driving was to start. This platform was located from the triangulation network; then by means of a transit set on the center line of the bridge, and using tapes for stationing, the piles were "spotted." Auxiliary platforms clamped to piles already driven were used to permit the pile-"spotting" crew to keep within a reasonable distance of the driver. Station points were checked at frequent intervals by tested tapes, as this method permitted very accurate pile spotting. Since all the piles could not be driven to the exact elevation required, some had to be cut off by means of an acetylene torch and air hammers.

After they had been driven, certain piles showing the maximum penetration per blow were selected for testing. A water tank was placed on top of an I-beam frame slipped over the top of the pile (Fig. 5), and was filled with water. Readings were made for various loads until a maximum of 90 tons was reached. Observations were taken for settlement under each increment of load. After the maximum was reached, the tank was emptied and readings were taken to determine how much, if any, the pile itself had been compressed or how much it regained under decreased load. It was found that piles which had a comparatively large penetration per blow while being driven showed only about ⅛-in. settlement by the maximum load of 90 tons.

*Floating Concrete Plant.*—Each of the two concreting plants was built on a special barge, 36 ft. wide by 91 ft. long, with a maximum draft of 7 ft. A stiff-leg derrick was placed at the rear for moving sand and gravel from scows moored on either side, to the bin over the 1-yd. concrete mixer; a 65-ft.

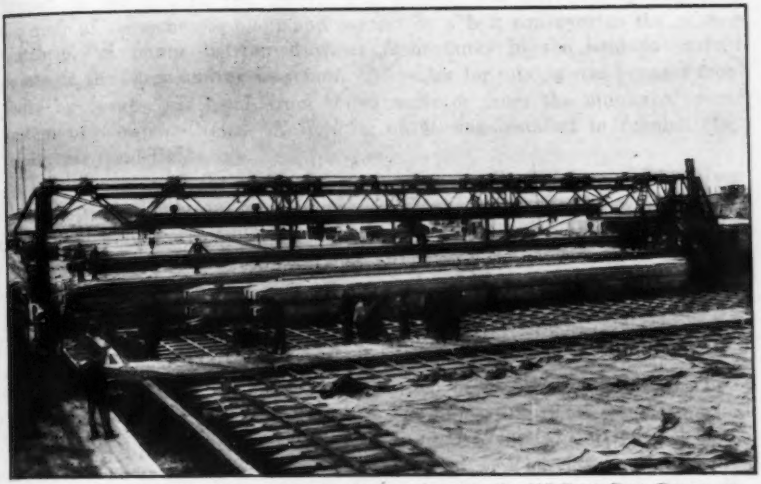

FIG. 3.—PILE-CASTING YARD, SHOWING GANTRY PICKING UP 115-FOOT PILE READY TO LOWER IT INTO STORAGE.

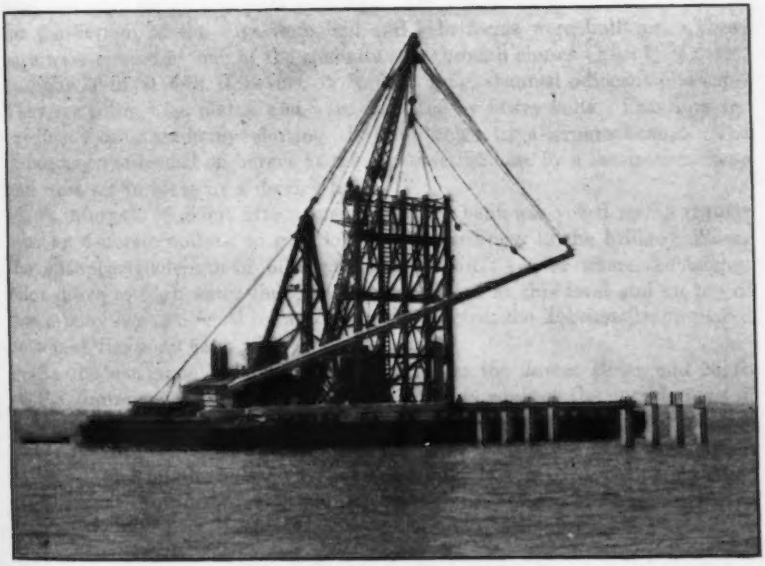

FIG. 4.—FOUR-LEAD PILE-DRIVER.

tower directly in front of the mixer hoisted the concrete to a distributing hopper on the face of the tower. The cement was delivered by barges at the rear of the concrete plant and carried by a belt conveyor to the mixing platform. A pump distributed water from tanks in the hold to various points on the barge and to the mixer. All water for mixing was brought from shore by barges. It came from tested wells or from the municipal water system of Newport News. A lighting outfit was installed to furnish electricity for flood lights, etc.

In the center of the barge was an anchor-handling device, power-driven through reduction gears to "nigger heads" at either side, by which means the plant could work itself along the bridge as desired. All this equipment was gas-driven and required about 250 h.p. in seven units of from 10 to 80 h.p. Wood-pile dolphins were driven at intervals of perhaps 1 000 ft. parallel to and about 500 ft. from the center line of the bridge. These were used for mooring the various equipment at night and also served as a point of attachment for the stern lines of the concrete rigs.

*Trestle Deck.*—The typical deck consisted of longitudinal I-beams upon which a 9-in. concrete slab was poured. The supporting trestle bent comprised four piles, 7 ft. on centers, capped by a concrete beam (Fig. 6) bonded to the pile by the pile steel itself. Forms for these caps were carried on timber yokes around each pile; on top of these yokes were laid two 6 by 10-in. timbers the full length of the bent. These timbers were likewise clamped by bolts to the piles and not only afforded a greater resistance to slipping under the concrete load, but also pulled the piles into line. On top of these timbers the forms for the bottom of the caps were laid and side forms were built up. These caps were poured by one of the concrete rigs through chutes (Fig. 7).

Four 30-in., 115-lb. I-beams, 43 ft. 9 in. long, spanned adjacent pile caps. They rested on base plates, and were anchored by heavy bolts. Provision for expansion was made by slotting the bolt holes in alternate beams. The I-beams were loaded on barges at the construction base by a locomotive crane and were set in place by a derrick boat.

At intervals of about fifteen spans, an extra bent was yoked to the regular bent by concrete collars, to give longitudinal stiffness to the bridge. Where the unsupported length of piles exceeded the limit set, or where the longest piles drove to high-water line, the cap was placed at this level and on top of this a pony bent stiffened by web walls was erected, the I-beams being placed on top of the pony bent.

As the clearance between curbs is 22 ft. on the James River and 23 ft. on the Nansemond River and Chuckatuck Creek, whereas the outside rows of I-beams are only 21 ft. on center, a small cantilever slab projected on each side. To support the forms for this, 4 by 8-in. outriggers were used; these, in turn, hung on the bottom flange of the outside row of I-beams and used the adjacent interior beams as points of reaction. On top of these outriggers, to support the floor forms, posts were placed, which also gave a means of bracing the outside of the curb forms (Fig. 8). For the interior panel forms between the I-beams themselves, 4 by 4-in. legs, with 2 by 6-in. headers, rested directly on the bottom flanges of the beams. Being of exact height they did

not require wedging. On top of both sets of jacks were laid panels constructed of ¼-in. tongue and groove material (Fig. 10). Because the curb was poured monolithic with the slab itself, some means for supporting the inside vertical forms was necessary. A steel frame was used supported from the outside form of the curb by angle brackets (Fig. 8). This obviated the necessity of having any wood or concrete blocks in the deck slab itself for the support of the form. The deck was smoothed by a finishing machine running on a track which was supported on chair-castings resting directly on the outside I-beams. After the finishing machine had passed, the track and castings were removed, and this section of the deck was hand-finished.

Reinforcing steel for the deck slab consisted of ⅝-in. bars running across the I-beams and raised over the points of support (Fig. 8). Concrete was poured directly from the barge as it pulled itself along. This method of operation obviated the necessity of wheeling the concrete, and thus permitted the finishing machine to follow closely behind the actual pouring. The slab was checked for bumps by light straight-edges, was given a float finish, and, finally, the float marks were rubbed out by dragging burlap over the surface. The deck was cured by being kept wet for fourteen days, and in warm weather was further protected against the sun by a burlap covering for several days.

*Bridge Structures.*—The piers supporting the trusses were in about 40 ft. of water and were supported on wood piles driven practically flush with the river bottom. On top of this piling were placed bell-shaped steel cylinders, two for each pier, extending to a point 4 ft. above mean low water. These cylinders flare from a diameter of 23 ft. at the bottom to one of 10 ft. at the water surface (Fig. 9). The piers comprised two cylinders with a connecting web-wall from Elevation + 4 to the bottom of the structural steel work. The foundation piers for the James River Bridge lift were 28 by 52 ft. at the river bottom, supported on wood piles, and were built inside single-wall, steel, sheet-pile coffer-dams. A concrete seal 15 ft. thick was placed inside these coffer-dams by tremie as in the case of the cylinder piers, after which they were unwatered and the piers themselves were built without difficulty. The supporting piers for the 90-ft. plate-girder spans were built on concrete piles capped at water level. Fig. 10 gives an idea of the extent and appearance of this entire structure.

The structural steel in the long spans was fabricated on falsework by means of a traveler, and each tower for the lift span was raised by a derrick designed especially for the work. The floor system of these truss spans was very simple and consisted of transverse floor-beams and four lines of stringers on which the concrete was poured, using forms similar to those for the trestle deck. The floor of the lift span had stringers placed much closer together, over which 2 by 8-in. creosoted planks were laid on edge. The wearing surface consisted of a 1½-in. layer of asphalt, fabricated in strips; these were laid very much like a plank flooring, the joints being poured with asphalt. All steel work was painted with one shop coat of red lead and two field coats of carbon paint, the final coat being black.

Each channel was protected by a fender 200 ft. long with 50-ft. flares. It was constructed of creosoted piling spaced 8 ft. on centers, capped by a 12

by 12-in. timber, with six 6 by 12-in. walings on the channel side. Dolphins of from 13 to 21 piles were driven at the break of the fender and at the end of the flares. The whole system was braced by a secondary row of creosoted piling.

Standard electrical navigation lights were supplemented by emergency oil lights. An aviation beacon with a direction marker was installed on the top of the north tower at the lift span to protect airplanes during night flying. The bridge proper was lighted by 150 Watt lamps with specially designed shields to prevent glare on the water. These lights were mounted on 18-ft. poles, approximately 260 ft. apart, as an integral part of the pipe railing. They were in a 3 300-volt series circuit with provision so that in case one bulb became "dead", the others would continue to burn.

*Completion.*—The first pile was driven on January 2, 1928, and the complete job was turned over to the owners on November 17, 1928. The equipment used in the river work consisted of more than sixty power boats, barges, dredges, and pile-drivers of various sizes. There were employed during the period of maximum activity more than 1 000 men on the whole work.

This project, costing about $6 000 000, was financed by Paine-Webber Company, of Boston, Mass. The J. E. Greiner Company, of Baltimore, Md., served as Engineers. The Turner Construction Company of New York was the general contractor and associated with it were the Raymond Concrete Pile Company, New York, concrete piles; Sanford and Brooks, Baltimore, dredging and deep-water piers; Virginia Bridge and Iron Company, Roanoke, Va., structural bridge work; and Roberts Paving Company, Salisbury, Md., concrete roads.

# DISCUSSION

WILSON T. BALLARD,[4] M. AM. SOC. C. E.—Two points mentioned briefly in this paper are worthy of further discussion, namely, preliminary studies of the subsurface conditions along the sites of the three bridges, and actual load tests made upon reinforced concrete bearing piles driven in the trestle portions of the Nansemond River Bridge and the James River Bridge.

Subsurface explorations of the bridge sites were made by borings, by driving timber test piles, and by driving reinforced concrete piles similar in every respect to the permanent piles in the structure. The borings and the behavior of timber test piles during driving furnished information upon which was based the tentative decision as to the general type and layout of the bridges, and the preliminary estimate of cost of the entire project. However, it did not furnish sufficiently reliable information upon which to base a final schedule of the lengths to be used in casting the concrete piles nor in determining the location of piles of various lengths in the bridges. For example, concrete pile lengths indicated by the behavior of timber piles driven in Chuckatuck Creek were from 15 to 20 ft. too long. As a further example, reinforced concrete piles could not be driven to more than one-half the desired penetration at the sites of the lift-span piers of the James River Bridge, whereas timber piles were driven successfully to the desired penetration of from 40 to 45 ft. through a hard blue marl. Had the material through which these piles were driven, been sand, it would have been possible to sink reinforced concrete piles to the desired penetration by the use of a jet.

The driving of test piles of the same size and kind as those designed for the finished structure furnished very reliable data for scheduling the pile lengths to be cast for various locations. Therefore, such piles were spotted at various points ahead of the location where driving of permanent bearing piles was in progress, and the casting schedule was governed by information thus obtained. As a result, there remained only one unused pile after all the permanent bearing piles had been driven.

In view of the great cost of making subsurface exploration of bridge sites similar in length and character to those of the three bridges of the James River Project, it is believed to be wise economy to confine the investigation to the driving of test piles exactly similar in every respect to those intended for use in the permanent structure. The pile-driver used on the test piles should be of the same type and weight as that to be used in driving the permanent piles. The information thus obtained may be supplemented by sufficient test borings to determine the character and depth of the underlying soil strata.

The load tests made on test piles and permanent bearing piles brought out interesting facts which add confirmation to the belief that the bearing value of large concrete piles driven in various types of soft material cannot be determined by the pile-driving formulas in general use. As stated by the authors, each test was made by mounting a steel tank upon the pile and

[4] Vice-Pres. The J. E. Greiner Co., Baltimore, Md.

filling it with water. The load was applied rapidly until it reached about 30 tons and thereafter more slowly. Observations of settlement were taken during and after loading. Of the eight tests made on permanent piles the time that elapsed during the application of the load was from 1½ to 3 days. The maximum test load was allowed to remain in place for 2 to 5 days, except in the case of two piles in the Nansemond River, from which it was removed after one day.

During the summer of 1927, several reinforced concrete test piles were driven along the site adopted for the James River Bridge, in that length of the river where borings and soundings indicated that greatest pile lengths would be required. This part of the river included a distance of about 6 000 ft. along the center line of the bridge and lay south of the present main channel. It may have been a deep channel in times past which was gradually deepened with the general subsidence of the eastern seaboard and filled up with clay and silt brought down by the river. These test piles varied in length from 90 to 114 ft. and were 24 in. square in cross-section. They were driven by a No. 1 Vulcan single-acting hammer, with a ram weighing 6 500 lb. and with a 3-ft. stroke. None of them could be driven to refusal in the soft bottom. Four were subjected to test loads sufficient to produce failure and the results were compared with calculated bearing values found by the use of the following pile-driving formulas:

Greiner formula:

$$P = \frac{1.07\, w\, h}{S + 0.1} \qquad (1)$$

*Engineering News-Record* formula:

$$P = \frac{2\, w\, h}{S + 0.1} \qquad (2)$$

Wellington formula:

$$P = \frac{2\, w\, h}{S + 0.1\frac{w}{w}} \qquad (3)$$

wherein:

$P$ = allowable design lead on pile, in pounds.
$h$ = stroke of hammer, in feet.
$S$ = penetration of pile, in inches, under final blow.
$w$ = weight of striking parts of hammer.
$W$ = weight of pile, in pounds.

Table 1 shows the results of the test compared with the calculated bearing values of the piles found by the use of Equations (1), (2), and (3).

These results showed the futility of attempting to govern the driving of the permanent piles by formula. As a result of these preliminary tests, it was decided to attempt to drive the permanent bearing-piles to a final set of not more than ¼ in. per final blow under the No. 0 Vulcan hammer (weight of ram, 7 500 lb., and stroke of 3.5 ft.).

When the driving of the permanent piles was commenced in the Nansemond River in January, 1928, it was soon evident that this could not be done with piles of reasonable length. It was then decided to continue driving, to observe and record carefully the behavior of the piles, and to subject each of

those that offered the least resistance to driving to an actual test load equal to twice the total load the pile would be required to carry in the finished bridge. Four of those driven in the Nansemond River were selected for test; two were 65 ft. long by 18 in. square, one, 70 ft. long by 18 in. square, and one, 95 ft. long by 24 in. square. Boring data obtained along the site of the bridge indicated that the three 18-in. piles penetrated from 10 to 15 ft. of soft mud and 30 to 35 ft. of soft blue clay or soft peat, while the 24 by 24-in. pile penetrated 15 ft. of soft black mud, 5 ft. of soft peat, 30 ft. of soft blue clay, 23 ft. of silty peat, and 15 ft. of hard, fine sand. However, the driving record of the 95-ft. pile would indicate that it probably did not penetrate much, if any, sand as it drove with comparative ease until its tip was 88.7 ft. below mean low water. The number of blows required to produce the final foot of penetration of each of these four piles is shown in Table 2 (Piles *A*, *B*, *C*, and *D*), together with the results of the load tests.

TABLE 1.—COMPARISON OF RESULTS OF ACTUAL LOAD TESTS WITH BEARING VALUES COMPUTED BY THE USE OF FORMULAS.

| Pile No. | Equation. | Penetration, *S*, in inches, under final blow. | Computed bearing value, *P*, in tons. | Maximum test load that caused no settlement, in tons. | * Load that produced failure, in tons. | Factor of safety based upon bearing value, computed by equations. |
|---|---|---|---|---|---|---|
| 1 | (1) | 0.5 | 17.4 | 20 | 85 | 4.9 |
| | (2) | | 32.5 | 20 | 85 | 2.6 |
| | (3) | | 14.7 | 20 | 85 | 5.8 |
| 2 | (1) | 0.095 | 53.5 | 30 | 121 | 2.3 |
| | (2) | | 100.0 | 30 | 121 | 1.2 |
| | (3) | | 17.4 | 30 | 121 | 7.0 |
| 3 | (1) | 0.25 | 29.8 | 30 | 85 | 2.9 |
| | (2) | | 55.7 | 30 | 85 | 1.5 |
| | (3) | | 17.0 | 30 | 85 | 5.0 |
| 4 | (1) | 0.226 | 32.1 | 30 | 103 | 3.2 |
| | (2) | | 62 | 30 | 103 | 1.7 |
| | (3) | | 15.3 | 30 | 103 | 6.7 |

* The load that produced failure is defined as that which produced rapid settlement that continued until part or all of the test load was removed.

After piles in the bent that included Pile *A* had been in place for 24 hours, the driver was placed on a pile adjacent to Pile *A* and an attempt was made to drive it farther. Fifty blows of the hammer drove the pile $\frac{3}{4}$ in. After a brief interval, twelve more blows produced no further penetration.

After the removal of the test load, Pile *D* (Table 2) recovered $\frac{1}{8}$ in., indicating that the permanent settlement caused by the load was $\frac{1}{2}$ in. The three 18-in. piles each recovered approximately $\frac{1}{3}$ in. on removal of the test load.

As a result of the tests of these four piles confidence was established in the fact that the load-carrying capacity of concrete piles that could be driven to a set of from $\frac{1}{2}$ in. to $\frac{3}{4}$ in. through strata such as were encountered in the bottom of the Nansemond River, would be safe for the loads to be imposed by the bridge in service.

During the driving of piles for the James River Bridge, several could not be driven to a final set of $\frac{1}{2}$ in. to $\frac{3}{4}$ in. with pile lengths of 115 ft. It was

decided, therefore, to make load tests on four of these piles which offered the least resistance to driving under the No. 0 Vulcan hammer, as used in Nansemond River. The four selected were each 24 in. square and 115 ft. long. According to borings made along the bridge site, each of these piles penetrated about 30 ft. of water, 50 ft. of stiff blue clay, from 5 to 10 ft. of soft blue clay, and from 20 to 25 ft. of sand. The behavior of these four piles during driving, however, would indicate that it was very doubtful if they penetrated any sand, as the number of blows of the driver for the final foot of penetration did not exceed ten for any of them. As the bottoms of the Nansemond River and James River, particularly the latter, vary greatly in character within short distances measured along the center lines of the bridges, and since they have at frequent intervals deep pockets of soft material, it seems quite likely that such pockets may have occurred at the locations of the four piles in the Nansemond and the four piles in the James River that were tested, without being indicated by the boring data.

TABLE 2.—RESULTS OF LOAD TESTS.

| Pile. | Length, in feet. | Size, in inches square. | Number of blows per final foot. | Maximum design load, in tons. | Test load, in tons. | Total settlement under test load, in inches. |
|---|---|---|---|---|---|---|
| *A* | 70 | 18 | 24 | 34.4 | 68.8 | 9/64 |
| *B* | 65 | 18 | 18 | 34.4 | 68.8 | 1/4 |
| *C* | 65 | 18 | 32 | 34.4 | 68.8 | 1/4 |
| *D* | 95 | 24 | 28 | 42.0 | 94.0 | 7/16 |
| *E* | 115 | 24 | 9 | 40 | 80 | 1/8 |
| *F* | 115 | 24 | 5 | 40 | 80 | 5/16 |
| *G* | 115 | 24 | 10 | 40 | 80 | 17/32 |
| *H* | 115 | 24 | 8 | 40 | 87.7 | 0 |

Table 2 shows a summary of the driving data and load-test results of the four piles (*E*, *F*, *G*, and *H*) in the James River Bridge. The test on Pile *H* is considered unfair because a severe storm with high wind prevailed. Heavy waves beat against the test tank and this probably caused the pile to loosen and settle as noted; settlement stopped when the filled test tank came to rest on adjacent piles. It should be stated that during the first three days of the storm, the pile settled only 1½ in. under a test load of 53 tons.

As a result of these tests it was decided that piles of lengths equal to those tested, and which behaved in a similar manner, could be relied upon to carry safely the maximum design load of 40 tons per pile. The three bridges have been in service since 1928 and there is no apparent evidence of pile settlement in any of them.

It is felt that the foregoing facts show that, when it is intended to support structures on piles, it is wise economy to limit subsurface exploration of sites similar to those described herein, to the driving of test piles identical in every respect to those intended for use in the permanent structure. Consideration of the results of the load tests, adds confirmation to the belief that, in pile-driving of the nature described, the various formulas in general use

cannot be relied upon to govern the driving, nor to determine the economic safe carrying capacity of the piles. Load tests should be made for this purpose.

WILLIAM WILLOUGHBY,[5] ASSOC. M. AM. SOC. C. E. (by letter).—The writer intends to confine his remarks principally to some amplification of that part of this paper pertaining to the structures over the navigable areas of the James River project.

To meet the requirements of navigation it was necessary to provide four openings, one in each of the bridges over the Nansemond River and Chuckatuck Creek and two in the bridge across the James River. (See Fig. 1.)

*Bridges Over Nansemond River and Chuckatuck Creek.*—The channels of the Nansemond River and Chuckatuck Creek were spanned with double-leaf deck-plate girder bascules of the rolling type, 110 ft., center to center of bearings. Each leaf was supported on a U-shaped pier founded on fifty-four 2-ft. square concrete piles, 80 to 85 ft. long.

The bridges are electrically operated and are equipped with solenoid service and emergency brakes. Limit switches cut out at the "open", "nearly open", "closed", and "nearly closed" positions, and an indicating light shows the interleave position of the shear locks. The bridge-operating circuits are connected in series with the warning devices and safety gates so that the bridge cannot be opened until warning is given and the gates are closed; nor can the gates again be opened until the bridge is entirely closed. The time required for operating the span is 1 min. Emergency operation by hand requires 12 min.

*James River Bridge.*—Nine 90-ft. through plate-girder spans across the south channel of the James River provide a horizontal clearance of 80 ft. and a vertical clearance of 25 ft. above mean high water. These spans are supported on rectangular piers on concrete piles. This opening is approximately 1 mile south of the main channel and provides access for small fishing boats to the large oyster beds on each side of the bridge.

The structure across the main channel of the James River consists of a 300-ft. vertical lift span. On each side of this span there are four 210-ft. truss spans and four 90-ft. through plate-girder spans (see Fig. 10). The truss spans are through bridges of the Warren type. The towers of the vertical lift span are connected to the adjacent 210-ft. spans in such a way that the vertical leg of the towers rests on the channel piers and the back leg frames into the span at the second panel point. This structure provides a minimum vertical clearance of 35 ft. for a distance of 1 980 ft. The lift span over the channel provides a horizontal clearance of 250 ft., a vertical clearance of 50 ft. above mean high water when closed, and a clearance of 145 ft. when open.

The piers adjacent to the channel are rectangular in shape; the base is 28 ft. wide and 52 ft. long, supported on 190 wooden piles, each 50 ft. in length. The piers under the truss spans consist of two cylinders, connected by a web wall above Elevation + 4.0. These cylinders are 10 ft. in diameter at the water-line and are flared to 23 ft. at the base. Each cylinder is supported on

[5] Res. Engr., The J. E. Greiner Co., Baltimore, Md.

forty-one wooden piles varying from 40 to 50 ft. in length at all but three piers, where the piles are from 70 to 80 ft. long. The plate-girder spans rest on rectangular piers supported by twelve concrete piles 2 ft. square.

The entire site of the piers was excavated to a depth of from 6 to 10 ft. below the bed of the river, or from 30 to 40 ft. below mean high water. The piles were then driven until their tops were approximately level with the original river bed, or to refusal. They were then cut off by divers at about 8 ft. above the bottom of the excavation. In the cylinders the piles were driven in three concentric circles the radii of which were 3 ft. 3 in., 6 ft. 6 in., and 8 ft. 9 in. The center of the piles in the outside circle was thus only 2 ft. 9 in. from the location of the steel cylinder. In the channel piers the piles were spaced in nineteen rows of ten piles each and came within 1 ft. 6 in. of the line along which the sheet-piling was to be driven. It will be noted that, due to the small amount of clearance between the piles and cylinders, or sheet-piling, it was necessary to use extreme care in locating and driving the piles so that the cylinders would go down over the pile clusters, and the sheet-piling (in the case of the channel piers) could be driven without interference.

A pile dock was built near the site of the piers from which measurements could be made for "spotting" the piles; these docks were located by triangulation because the channel is a mile from the nearest shore. Except in the case of the three piers in which 70 to 80-ft. piles were used, the piles were driven through a steel tube 26 in. in diameter. The tube was provided with guides that fitted the leads of the pile-driver and was so constructed that it could be raised or lowered. The pile-driver was located at the correct point, and the tube was lowered until it rested on the bottom of the excavated hole. It was long enough to reach from this point to about 5 ft. above the surface. The pile was then placed in the tube and driven by means of a follower until its top was at the desired elevation. The required length had been previously determined by driving test piles at the site of each pier. In the case of the long piles sufficient penetration was secured, before it was necessary to use the follower, to guide them down to their correct positions. The steel cylinders were then lowered over the pile clusters, guided by divers or, in the case of the channel piers, coffer-dams were constructed. In no case did the piles interfere with these operations and this good fortune was due to the care with which they were driven. A submarine seal was then placed by means of a "tremie" pipe so that the piles were embedded. In filling the cylinders, the concrete was brought to within about 15 ft. of the surface in one continuous operation. A 15-ft. seal was placed in the channel piers. The coffer-dams and cylinders were then pumped out, and the remainder of the pier was constructed in the open. The coffer-dams of the channel piers were single-wall, steel, sheet-pile dams, securely braced, and were unwatered to a depth of 30 ft. The dams were very tight and were kept dry with very little pumping.

At the site of the cylinder piers, it was necessary to construct heavy docks to which the steel cylinders were secured. This prevented the cylinders from rising as the concrete, in its fluid state, rose in the flared section.

The vertical lift span is of the direct-drive type, thus eliminating the heavy machinery required for its operation from the span. On top of each tower is a

house in which is located the machinery for the operation of the span. The machinery consists of a gear train on each tower, connecting the motors directly to a ring gear on the two 11 ft. 6-in. sheaves over which the cables pass. One end of each cable is attached to the span and the other to the counterweights. The friction between the cables and the sheaves causes the span to raise and lower when the sheaves rotate. There is no slip in the cables.

The four 40-h.p. motors (two on each tower) are synchronized in pairs. As only one pair of motors is required to operate the lift bridge, the brakes on the other pair act as emergency brakes. One pair of motors is used to operate the bridge on alternate days so as to insure the correct performance of either pair at all times.

The operation of the span is controlled from the operator's house which is on a level with the roadway, through a single drum-type controller. The controller is so connected that between the position of "nearly open" and "open", "nearly closed" and "closed", which represents about 5 ft. of vertical movement, only a small amount of current can be furnished to the motors. This prevents the sudden seating of the bridge by a careless operation, which would be serious because the weight of the span and counterweights is about 2 000 000 lb. The span is also equipped with air buffers at top and bottom.

The lift span is equipped with a self-leveling device operated by motor-generator sets such that, when the bridge becomes 18 in. out of level, additional resistance is automatically thrown in series with the motor, thus slowing down the motor on the side that is leading.

In addition, in case the automatic device breaks, there is an indicating dial, 18 in. in diameter, placed at the level of a man's eyes over the control drum. This is equipped with two superimposed hands, one red, indicating the position of the far end of the span, and the other black, indicating the position of the near end. Just below the dial are two push-buttons, one painted red corresponding to the red hand, and the other black, so that the operator can throw in additional resistance in the circuit with the leading motor, thus slowing it down. It is necessary for the span to get 6 ft. out of level before the guide-shoes on it will jam. Traffic is protected by alarm bells, blinking lights, and safety gates about 200 ft. from the lift span.

R. C. Wilson, Esq., and Herbert B. Pope, Assoc. M. Am. Soc. C. E. (by letter).—The discussions have really amplified the contents of this paper and, therefore, there is no need for a reply by the authors except to express appreciation to those who submitted them.

Mr. Ballard has brought out very clearly the fact that the various formulas in general use cannot be relied upon to govern the driving or determine the safe carrying capacity of the large concrete piles which were used in connection with this work.

The discussion by Mr. Willoughby has clarified certain details of design that had merely been outlined in the paper. His comments in regard to the machinery for operating the lift span are of particular interest in view of the first applications of direct drive to large lift spans.

Paper No. 1769

# FACTORS GOVERNING THE LOCATION OF AIRPORTS[1]

By Donald M. Baker,[2] M. Am. Soc. C. E.

With Discussion by Messrs. Stephen Child, Morris Knowles, George D. Burr, N. H. Angell, J. Ogden Marsh, Archer R. Norcross, John Nolen, S. N. Grimm, R. U. St. John, John F. Partridge, William J. Fox, Perry A. Fellows, W. W. Crosby, E. K. Smith, Clyde M. Wood, and Donald M. Baker.

Synopsis

The rapid growth of aerial transportation in the United States since about 1924, and, particularly, the wide interest shown since the spectacular trans-atlantic flight of Colonel Lindbergh, have developed the need of landing fields and airports in many communities. It is the purpose of this paper to outline, briefly, those things which should be taken into consideration when selecting a site to be used as an airport. The factors are discussed in detail and a method of rating is suggested by which various sites under consideration may be compared, one with another.

Matters pertaining to layout or design of fields are not discussed, except as they may affect the general size. While the subject-matter herein presented applies primarily to airports which will be used by heavier-than-air land planes, much of it applies also to the selection of terminal facilities for seaplanes. The development of lighter-than-air craft, or dirigibles, has not yet progressed to the stage where it has become necessary to provide facilities for them upon a large scale, and sufficient experience has not yet been acquired in their operation from a commercial standpoint to warrant the consideration herein of landing fields for this type of aircraft.

[1] Presented at the meeting of the City Planning Division, San Diego, Calif., October 4, 1928.

[2] Cons. Engr., Los Angeles, Calif.

Air transportation offers the human race a new means of mass transportation, in addition to the railroad and the automobile. The civil engineer has played an important part in developing railroads, highways, and terminals, and he has his proper place to take in the field of air transportation. Travel by air is more closely akin to water transport than to land transport. The right of way is not rigidly fixed, and the only developments necessary in the establishment of airways are provisions to insure safety in flight and maintenance of proper direction, plus terminal facilities. Just as ships must be provided with harbors or docking facilities, so must aircraft be provided with landing facilities.

An airport, however, must be considered as more than a mere landing field for aircraft. It is a real terminal or harbor equipped with all the necessary facilities and utilities for handling aircraft, for passengers and cargo, for storage and repair of planes and engines, for testing them, etc. It must have all the characteristics and accessories of any terminal as well as other features peculiarly incident to air traffic.

The users of an airport may be roughly classified as:

1.—The Federal Government, for military and naval planes, etc.
2.—Commercial transport organizations.
3.—Operators of private, pleasure, and business planes.
4.—Flying schools.
5.—Operators of commercial and sightseeing planes.
6.—Aircraft manufacturers and allied industries.

At present, aviation occupies the status of an "infant industry" operated in small units. As such it merits public subsidy. The acquisition and operation of airports by public agencies, such as cities and counties, are fully justified on the same grounds as the public development of harbors and highways. Where nominal fees are charged for the use of space and facilities of an airport, its public development forms a most reasonable and logical type of local subsidy. When traffic increases in volume, as it is bound to do, there is little question but that publicly owned airports will become self-sustaining.

## Uses of Airports

The primary excuse for the acquisition of an airport by a public body lies in the need for assisting and encouraging air transportation. The question will naturally arise as to whether one or more airports should be acquired in any community. Various estimates have been made concerning the future density of aircraft in this country, ranging from 1 ship per 100 persons to 1 per 1 000.

In the smaller communities undoubtedly all types of aeronautical activities will be concentrated in one airport. However, in larger centers, if not now, at least in the near future, it will be essential to segregate the different types of use, selecting one large site to serve as a major traffic terminal, testing and industrial field, and, possibly, a passenger and cargo depot, with one or more additional sites for private, commercial, and sightseeing planes, flying schools, and similar uses. Where this possibility exists, the

subject should be given considerable study by the local authorities, and a program adopted for the establishment of an adequate number of airports to serve the area.

### Selection of Site

To the average layman or amateur any large open area, fairly level, ranging in size from 100 to 1 000 acres, near the city, and available at a price, is a suitable site for an airport. On the contrary, the selection is a highly technical problem involving knowledge of aviation, city planning, transportation, meteorology, finance, and law, and should only be attempted after adequate investigation and study by experts thoroughly familiar with the subject.

Inasmuch as the capital outlay for land to be used for an airport site is considerable, and usually forms a large proportion of the total investment, and as a proper location for such a site will have much to do with the successful development of aeronautics in the community, the small cost and even short delay incident to technical study and investigation prior to purchase always will be warranted.

Where meteorological conditions vary greatly within a radius of from ten to twenty miles from the center of the community, it is desirable that a study of such conditions be carried on at all sites under investigation for a considerable period—if possible, a year. This study should be directed toward securing data on wind direction and velocity, and variations of these factors, visibility, occurrence of fog, rainfall, air turbulency, and related matters. If time is short a study of these elements for a period extending over a few months will be of great value, particularly when the results can be correlated with data from the U. S. Weather Bureau Stations in the vicinity. Other factors, such as present and future accessibility, transportation, trend of surrounding development, etc., do not take as long to investigate, and their study may be carried on while the meteorological observations are being made.

### Factors Governing Location of Site

Factors affecting the site group themselves into three classes, namely, those dealing with the general location, those dealing with the site itself, and those dealing with the primary use to which the site is to be put.

After it has been determined as to whether one or a number of airports are to be acquired, and also as to the respective use or uses which will be made of each location, the sites should be studied individually from the following standpoints:

(*a*)—Topography.
(*b*)—Physical Features.
(*c*)—Meteorology.
(*d*)—Location with Respect to Community Served.
(*e*)—Transportation Facilities.
(*f*)—Accessibility.
(*g*)—Legislative Control.
(*h*)—Utilities Available at or near the Site.
(*i*)—Cost.
(*j*)—Miscellaneous.

These factors will be discussed in detail. The requirements set up are basic for any site, except where noted, and are the maximum to be desired.

(*a*)—*Topography.*—Topography includes both that of the site and that of the surrounding territory.

The surface of the landing field should be flat, or of such a character that it can be made flat at nominal cost. Rolling or broken country is undesirable on account of grading costs. The surface of the field should have a general slope to facilitate drainage, ranging from a minimum of 0.5% to a maximum of from 1.5 to 2.0 per cent.

Since most accidents to planes occur within the first few hundred feet after they leave the ground, open spaces to the windward of the airport are desirable for use as emergency landing fields in case of engine trouble or other difficulties occurring immediately after the take-off.

Distinctive landmarks should exist, such as stream channels, highways, railroads, and similar topographical features. These will readily identify the airport to the strange flier approaching the field from the air, and will also assist the familiar pilot in locating it in bad weather.

The surrounding topography should be of such a nature that reasonable future expansion of the airport can be made at a cost which will not be prohibitive.

(*b*)—*Physical Features.*—The site must be protected from overflow by flood waters. The surface of the landing field should be kept free from mud or standing water at all times; this requires a quick draining soil of light texture underlaid by an open subsoil. Clay or other heavy soils that do not yield moisture readily may require surfacing or an expensive tile drainage system.

Where a field is used extensively it will become dusty in dry weather if the soil is of a friable character. Preventive measures in this respect are quite costly. In uncultivated country, wind storms may cause objectionable dust haze with resulting poor visibility.

If turf or sod are to be used on the runways or landing areas, a fertile soil is necessary and, where rain does not fall throughout the year, water must be available for irrigation. With other soil, landing strips must be built of concrete, cinders, slag, gravel, asphalt, or other suitable material.

High-tension wires, buildings, poles, and smokestacks in the vicinity of the site constitute serious hazards and are very expensive to remove.

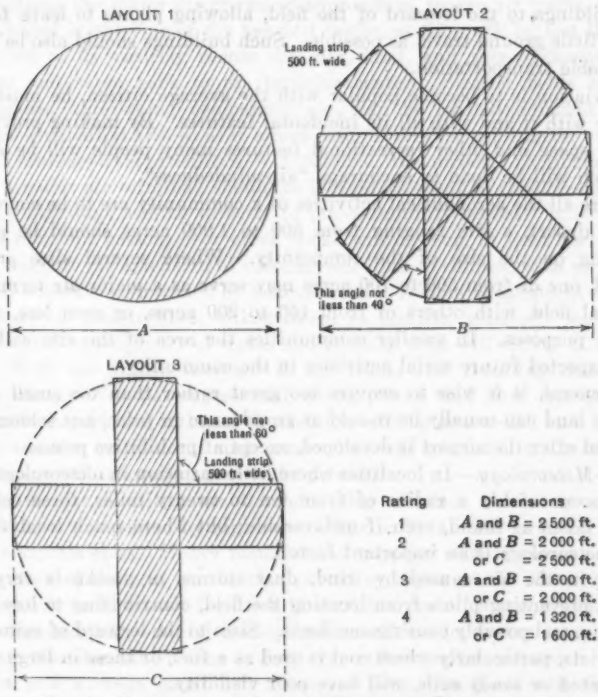
Care must be given to the location of future highways, as no traffic arteries should be allowed to cross the site, and if the airport is located in the path of such an artery, expensive location around the site may become necessary.

The U. S. Department of Commerce has developed a system of rating airports, based on the following:

1.—General facilities and equipment.

2.—Size of landing area.

3.—Night lighting equipment.



Six ratings for size are given as will be shown. In addition, the following basic requirements must be met:

(*a*) The field must be approximately level, with a maximum slope at any one point of less than 2.5% and an average slope not in excess of 2 per cent.

(*b*) Clear approaches must exist from all sides of the field so that no obstacle projects above a 1 to 7 grade from the exterior boundaries of the field.

Certain ratings have been adopted by the Aeronautics Branch of the U. S. Department of Commerce, as to the site of landing fields.

For Rating 1 (Fig. 1), the field must have 2 500 ft. of landing area in all directions; or landing strips, 500 ft. wide, permitting landing in at least eight directions, the strips to be at least 2 500 ft. in length and crossing and converging at angles of not less than 40 degrees.

| Rating | Dimensions |
|---|---|
| 1 | *A* and *B* = 2 500 ft. |
| 2 | *A* and *B* = 2 000 ft. or *C* = 2 500 ft. |
| 3 | *A* and *B* = 1 600 ft. or *C* = 2 000 ft. |
| 4 | *A* and *B* = 1 320 ft. or *C* = 1 600 ft. |

FIG. 1.—DIMENSIONS OF LANDING FIELDS FOR RATINGS BY THE U. S. DEPARTMENT OF COMMERCE.

For Rating 2, the field must have 2 000 ft. of landing area in all directions; or landing strips, 500 ft. wide, permitting landing in at least eight directions, the strips to be at least 2 000 ft. long and crossing or converging at angles of not less than 40°; or two landing strips, 500 ft. wide and 3 000 ft. long, per-

mitting landing in four directions, the strips crossing or converging at angles of not less than 60 degrees. Comparable details for Ratings 3 and 4 are also given in Fig. 1.

Rating 5 includes fields not having minimum dimensions of a No. 4 rating for size, but which the Department considers safe for the use to which they are put.

Finally, fields not considered safe for operation of aircraft, but desiring a rating, will be rated "0" on size.

The dimensions given must be increased where fields are at altitudes in excess of 1 000 ft. above sea level.

In addition to the area necessary for runways, space is required for shops, hangars, and administration buildings, and if the airport is to be used for industrial purposes it may be advisable to provide space which may be leased to these industries. It is advisable to locate shops, hangars, and administration buildings to the leeward of the field, allowing planes to leave for flying with as little ground travel as possible. Such buildings should also be adjacent to available transportation.

If aviation is to become popular with the average citizen, he must become familiar with it and with all its incidental features. By making provision for parking space and other recreational features many people will be attracted and much will be done to encourage "air-mindedness".

Where all the aeronautical activities of a community are to be concentrated on one airport, a site ranging from 500 to 1 000 acres should be provided, depending on the size of the community. Where several sites are to be acquired, one of from 500 to 700 acres may serve as a major air terminal and industrial field, with others of from 150 to 200 acres, or even less, used for different purposes. In smaller communities the area of the site will depend on the expected future aerial activities in the community.

In general, it is wise to acquire too great rather than too small an area, as excess land can usually be re-sold at an advance in price, but seldom can be purchased after the airport is developed, except at prohibitive prices.

(*c*)—*Meteorology.*—In localities where little variation in meteorological conditions occur within a radius of from ten to twenty miles, these conditions must be taken as found, even if unfavorable; but where much local variation exists, meteorology is an important factor.

Haze in the air caused by wind, dust storms, or smoke is very objectionable, preventing pilots from locating the field, contributing to loss of time in landing, and possibly causing accidents. Sites to the leeward of manufacturing districts, particularly where coal is used as a fuel, or those in large areas of uncultivated or sandy soils, will have poor visibility.

Fogs are of great menace to aerial navigation. Ground fogs hinder safe landing and take-off, while high fogs cause loss of bearing by pilots, and delay in arrival. Airports located in fog belts are extremely undersirable for use by commercial or transport planes which operate on a fixed time schedule, although they may not be quite so objectionable to occasional fliers, sightseers, or pleasure planes, which can choose their time of flight.

A plane must take off and land, flying directly into the wind. Sites which are subject to quickly shifting winds require great care in keeping all the runways clear. Strong winds may cause damage to planes parked outside of hangars and necessitate increase in storage facilities. "Bumpy" air, caused by cross-air currents which result from unevenness of surface topography or nearby hills, makes for difficulty in control of ships, and is extremely dangerous where the field is congested.

(*d*)—*Location with Respect to Community Served.*—The airport should be located so that flying over the residential section of the community can be kept at a minimum. There is an increasing tendency in cities to prohibit air traffic over residential areas except at very high elevations, or to restrict air travel over certain routes. These restrictions will impair the efficiency of any field within or near such residential areas, or limit the line of expansion of such development.

By studying the major directions of approach of future air traffic, the site may be located in the line of the heaviest traffic, as time will be lost if planes are required to fly entirely across the city, land, and then transport their passengers and cargo back to the business center. Smaller fields used for private planes, sightseeing companies, etc., can be located adjacent to the better class residential area so as to afford ready access for passengers.

(*e*)—*Transportation Facilities.*—If possible, the airport, particularly one used for a major air terminal, should be located adjacent to rapid transit lines and major highways leading directly to the community served. It is improbable that sufficient passenger or other traffic will develop, at least for years to come, to warrant the extension of existing rail lines to connect with an airport. The usual schedule maintained by a steam road is seldom adequate to serve the field, but rapid transit lines, either steam or electric, generally maintain a schedule which in frequency of trains and running time will satisfy all requirements. With the future increase in air traffic and resulting decrease in carrying charges for passengers and cargo, cheap and fast transportation between the airport and ultimate destination will be demanded, and this only rapid transit can furnish. If such cannot be made available, a regular motor transport line will ultimately have to be provided.

While freight facilities are desirable they are not absolutely essential, provided the site is served by highways. Practically all the cargo carried will be of the express class. Heavy material and supplies used in the construction and operation of the port can be transported by motor truck. Motor bus lines supplementing rapid transit facilities, if available, are a feature of added value.

(*f*)—*Accessibility.*—Aerial transportation will be dependent largely for its success on the element of time saving over rail or motor transport. Present schedules now average about 100 miles per hour, and these will shortly be increased by 25%, or more. The time element must be considered, however, as being from point of origin of trip, by passenger or cargo, to the point of ultimate destination. This time divides itself into that consumed between the airport and points of origin and destination, and that consumed by air travel.

In time, any site served solely by highway transportation will ultimately become farther and farther away from the business center, due to increasing

traffic congestion, as American cities do not appear to be able to provide highway facilities fast enough to keep ahead of the increasing density of motor traffic. A site served by rapid transit, however, will always remain at a constant time distance from the business center, and with improvement in rapid transit facilities may approach closer to it in point of time.

For short distances between ultimate termini, the time saved by air over rail transport is small. The curves of Fig. 2 indicate that great saving in time through use of air over rail transport only occurs on long hauls, probably in excess of 500 miles for passenger travel and 1 000 miles for other cargo. The added cost of air over rail transport will undoubtedly limit its extensive use to the longer hauls.

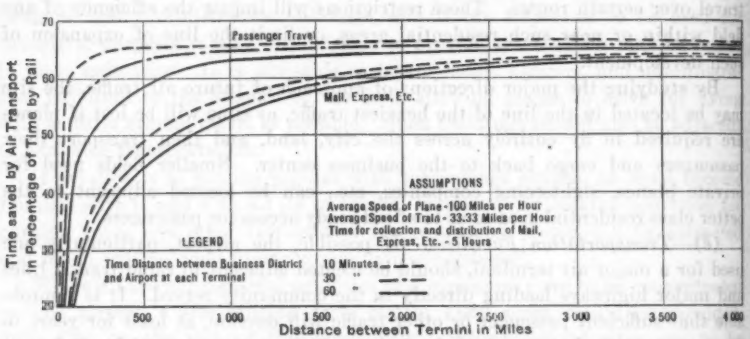


FIG. 2.—SAVING IN TIME ACCOMPLISHED THROUGH USE OF AIR TRANSPORT INSTEAD OF RAIL TRANSPORT.

These curves also show that undue weight is given to the necessity of locating an airport which is to be used as a major traffic terminal close to the business center. Land values in general decrease with an increase in distance from the center of the community. A careful study must be made of the relationship between the time saved through the selection of a close-in site as against the increased cost of such location. This point is of great importance.

Due to the psychology of the air traveler, however, it is not advisable to locate an airport more than from 30 to 40 min. from the business center if it is to be used as a major air terminal, unless land values at this distance are prohibitive, in which case a small close-in port may be chosen as a depot with a larger field for service, storage, etc., selected in an area of cheaper land.

Sites used for private planes should be within fairly close distance of the residential communities. Otherwise, the extensive use of planes by private parties will be discouraged. The plane owner does not care to spend an hour traveling out to the airport for a flight of like duration.

(*g*)—*Legislative Control.*—Police protection and regulations should be available at the airport. The development of the area surrounding the site must be subject to such control as will prevent the encroachment of residential areas or of obnoxious industries which might impair the usefulness of the field. It is not essential that the airport be within the corporate limits of a city which owns and operates it, provided proper authority exists allowing

ownership and operation of such facilities outside of city boundaries, and that proper control may be had or secured over the policing, zoning, building regulations, etc., in the area surrounding the site.

(*h*)—*Utilities.*—Any site considered should have electric power, water, fuel, telephone, and telegraphic connections with surrounding centers, and should be accessible to supplies of gasoline, oil, and other necessities. Where the field is to be used for industrial purposes, or when workmen are to be employed, housing conditions for workers may be an important consideration.

(*i*)—*Cost.*—To afford a proper basis for comparison between different sites, and to evaluate their relative accessibility, there should be included in the cost of each site, in order to reduce such cost to a common denominator, the following:

1.—Land.
2.—Grading, leveling, surfacing, draining, and tiling.
3.—Removing hazards and obstructions.
4.—Bringing transportation and traffic facilities adjacent to site.
5.—Bringing necessary utilities adjacent to site.
6.—Providing adequate fire protection.
7.—Financing, condemnation, etc.

(*j*)—*Miscellaneous.*—Undoubtedly, certain other considerations entering into the problem of selecting a site from a local standpoint, may be peculiar to the community to be served, and do not come under the headings given. Local politics, while they should be kept out of consideration, nevertheless are a factor in it. All these latter matters are grouped under the heading of miscellaneous factors.

### Basis of Comparison of Different Sites

It will be well-nigh impossible to find a location for a municipal airport which is perfect from all standpoints. When various sites are under discussion, certain factors are likely to be given undue prominence in reaching a decision, and the following method is suggested as a means of arriving at the most desirable site.

Every site should be considered separately from each of these ten standpoints, and each factor given a rating on the following basis:

| Rating. | Percentage. |
|---|---|
| Excellent | 90 to 100 |
| Good | 80 to 90 |
| Fair | 70 to 80 |
| Unsatisfactory | Below 70 |

Little consideration should be given a site where factors of meteorology and accessibility fall below 90%, or where topography, physical, or transportation features fall below 80 per cent.

Since not all the factors considered are of equal importance they should be given different weights. The following are suggested as suitable of application where a single airport is to be selected and used for a major traffic terminal:

| Factor. | Weight. |
|---|---|
| (*a*).—Topography | 10 |
| (*b*).—Physical features | 14 |
| (*c*).—Meteorology | 14 |
| (*d*).—Location with respect to community served | 10 |
| (*e*).—Transportation facilities | 11 |
| (*f*).—Accessibility | 11 |
| (*g*).—Legislative control | 5 |
| (*h*).—Utilities available at or near site | 5 |
| (*i*).—Cost | 10 |
| (*j*).—Miscellaneous | 10 |
| Total | 100 |

By multiplying the percentage rating given each factor for the site under consideration into the weight assigned that factor, and taking the total of the resulting figures, a final rating for each site can be found. The weights given may be varied somewhat, depending on the use to which the site is to be put.

## DISCUSSION

STEPHEN CHILD,[3] M. AM. SOC. C. E.—Tucson is a thriving city of about 40 000 population, in Southern Arizona, approximately seventy miles from the Mexican line. It has been actively and definitely "air-minded" for some time, as the following facts furnished the speaker by the Secretary of the Tucson Chamber of Commerce, will abundantly testify.

The first municipal aviation field in Arizona, if not in the United States, was established at Tucson, and began to operate as such in 1917. It had an area of 80 acres and cost $7 000. It is about 2 miles directly south of the city on a site selected by Eric Nelson, one of the world-famous fliers. About 1922, the Chamber of Commerce, in co-operation with the City, erected a hangar and a building for quarters for the employees who were furnished by the U. S. Army Air Service, and a lease was made by the City to the Air Service for the operation of the field.

This original airport of Tucson is still owned by the City and is leased to a commercial aviation company, which is offering to the public aviation training as well as taxi service. This provision meets the requirements of Mr. Baker, who recommends that such features should not be permitted at the more official airport of the city.

In 1925, however, the Chamber of Commerce took much more important action and was able to secure the passage of a bill by Congress, setting aside two full townships (1 280 acres) only a little more than 4 miles from the center of the city. This land has been leased to the City of Tucson for twenty years, with an option to renew the lease for another twenty years, for the exclusive purpose of developing aviation. It will be seen that the important provision of permanency stressed by the author, is assured.

The tract is very nearly level, having a gentle downward slope from east to west of only about 1 per cent. There is no obstructing vegetation, no ledge or boulders to be removed, or important gullies to be filled up. There is merely the customary desert growth of mesquite and cactus. The topographical conditions, therefore, are nearly perfect.

Of this large area 240 acres have now been quite fully developed by the City of Tucson and the Army Air Service, at a total cost of about $30 000—a minimum figure. A hangar has been erected, attendants' quarters have been constructed, a pumping plant for water supply has been installed, and a Government Radio Meteorological Station has been set up and fully equipped. By means of a public subscription, aided by the City Government, sufficient funds to install a beacon light and flood lighting equipment have been raised. The Army Air Service keeps a sergeant and one private stationed at the port to service all Army planes. A large gas storage equipment has been installed by the Government, and private oil companies have set up storage tanks on the field for commercial planes. The equipment is, therefore, practically perfect for a port of this size, and there is ample opportunity for its extension.

[3] Landscape Archt.; Consultant in City Planning, San Francisco, Calif.

The airport is used jointly by Government and commercial planes, under the direction of the Army Air Service and the supervision of the City itself. Legislative control as emphasized by Mr. Baker, therefore, is well provided.

As to accessibility it will be noted that the Tucson Airport is only about five miles from the heart of the city over existing rectangularly arranged roads, which are well paved. It should be emphasized, however, that the main line of the Southern Pacific Railroad crosses this airport at its southwest corner, and that there is now a flag station stop at this point, which can be readily made more important when the need arises. There is no doubt that there will be constructed in the near future a diagonal avenue parallel to the existing railroad tracks, shortening the distance from town by at least a mile.

One of the well-known aviation transportation companies operates a passenger service between this port and Los Angeles, Calif., three times a week, a stop being made at Phoenix, Ariz., en route. Connections have been established so that it is possible now to leave Tucson at 8:00 A. M., arriving at Los Angeles at about 1:00 P. M., and connecting with the airplane service operating between Los Angeles and San Francisco so as to arrive there in the early evening.

Leases for hangar space are arranged with the City and the airport is now so well known and completely equipped that it has a double "A" rating, and is considered one of the best inland airports of the country. Between January 1 and October 1, 1928, the registration of the airport shows more than 900 airplanes using its facilities, and during the month of September, 1928, 275 were registered. The City of Tucson has appropriated for the fiscal year 1928-29, funds for the construction of a building to be used as a waiting-room, ticket office, and lunch room.

The author has suggested a means of comparing different sites, and the speaker has thought it interesting to develop the rules given, as shown in Table 1.

TABLE 1.—COMPARATIVE RATING OF AIRPORT AT TUCSON, ARIZ.

| Factor. | Weight. | Percentage. | Rating. |
|---|---|---|---|
| (*a*) Topography | 10 | 100 | 1 000 |
| (*b*) Physical features | 14 | 100 | 1 400 |
| (*c*) Meteorology * | 14 | 95 | 1 330 |
| (*d*) Location with respect to community served | 10 | 95 | 950 |
| (*e*) Transportation facilities | 11 | 95 | 1 045 |
| (*f*) Accessibility | 11 | 95 | 1 045 |
| (*g*) Legislative control | 5 | 100 | 500 |
| (*h*) Utilities available at site | 5 | 100 | 500 |
| (*i*) Cost | 10 | 90 | 900 |
| (*j*) General desirability from all standpoints | 10 | 95 | 950 |
| Total | 100 | .... | 9 620 |

* No fogs; sun shines on an average of 358 days in the year.

In other words, the field is 96.2% ideal, which is a very high rating. It will be interesting to determine the ratings of other airports by this means of comparison. The speaker hopes that Mr. Baker will submit such comparisons,

but it seems clear that for a comparatively small community of less than 40 000, the facts indicate a very creditable state of affairs for Tucson as to aviation and airports.

MORRIS KNOWLES,[4] M. AM. SOC. C. E.—It is well to emphasize the fact that airport location, like other new municipal problems, is simply one of city planning, and as such it should be solved. It is inconceivable to consider an airport as wisely located, if in the selection of a site the fundamental principles of good community planning have been violated. This has been stressed by Mr. Baker. A definition has been given[5] that:

"An airport is a locality, either water or land, adapted for the landing or taking off of aircraft, and which provides facilities for shelter, supplies, and repair of aircraft; or a place used regularly for the receiving or discharging of passengers or cargo by air."

Safety and convenience, in the provisions for the landing or taking off of planes, are matters of first importance. However, aside from possible emergency fields, which may be for this purpose only, an airport assumes an objective for traveling planes other than that of landing; or to reverse the situation, a plane in the ordinary course of events must have some object in being at a certain location other than the mere fact of desiring to leave there. In short, this reduces to the statement, by way of emphasis, that while air transportation may be considered more or less in its infancy, its real importance as a public carrier certainly will increase and, with it, the necessity of locating the airport with respect to traffic-handling facilities and other similar features.

Mr. Baker has stressed ten features requiring consideration in determining ratings for locations offered as sites for airports. In reference to five of these, he states that little consideration should be given to a site which does not measure up to 80 or 90% of the standards given for them in the tables. Although he does not say so, it may be assumed that he considers others of less importance. This suggests the possible elimination of such minor items as Factors (*g*) and (*j*) in the rating and the substitution of others of more importance. For example, there are two such items discussed under the heading of "Topography" (Factor (*a*)): Those of open spaces for emergency landing fields and landmarks for identification.

The selection of a site for the Pittsburgh (Pa.) Airport, by a Committee of the Chamber of Commerce, was made by the use of a rating schedule, developed after approximately two hundred sites had been listed for consideration. Many of these had been suggested by the public through a questionnaire which was sent out for the purpose. This, in order to confine suggestions within reasonable limits, was made up so as to attract attention to the salient factors which would be considered in the choice.

The study of this large list of possibilities was simplified by the preparation of charts which enumerated, on a comparative basis, the desirable and undesirable features of each site. This naturally eliminated many because of some outstanding objection or obstacle. The rating schedule was then developed and applied to the more desirable sites after they had been inspected

[4] Pres. and Chf. Engr., Morris Knowles, Inc., Pittsburgh, Pa.
[5] *Bulletin No. 40*, U. S. Dept. of Commerce.

from the ground and air. Thus, as the study progressed, eliminations increased, until only a few sites remained for consideration.

Such a rating table suggested as an aid in the final analysis, gives the weights of the various factors considered as important under the particular circumstances. It is as follows:

| | Weight. |
|---|---|
| (1) Size, physical features, and freedom from obstructions.. | 20 |
| (2) Distance from business district and City Post-Office.... | 15 |
| (3) Accessibility by various transportation methods..... | 14 |
| (4) Possible emergency fields existing near-by..... | 12 |
| (5) Railroad connections, with sites for shops..... | 10 |
| (6) Freedom from wind, fog, and smoke..... | 9 |
| (7) Property and cost of converting (quite approximate)... | 8 |
| (8) Seaplane facilities in proximity..... | 5 |
| (9) Distinguishing landmarks for visiting pilots..... | 4 |
| (10) Water supply and fire-fighting facilities..... | 3 |
| Total ..... | 100 |

While such ratings form an important basis for selection, many general factors will still remain to be evaluated, and the final recommendation should depend on the experience and judgment of those who are attempting to make the selection.

In discussing the development of airports it is important to realize that the problems differ in coast and inland cities, not only because of topography, but because of location. For example, Mr. Baker emphasizes the desirability of locating the field on the side of the city from which the aircraft will approach. This is not important for most inland locations, as the approach may be from any direction and, probably, in the majority of instances, unless detours are made, it will be necessary to fly over the city either approaching or leaving the field. At the same time it is possible that where the routes are at right angles—east and west and north and south—a location adjacent to the city at one of the intermediate points of the compass would make it possible to avoid flying over the built-up territory.

Mr. Baker refers to the undue weight which often is given to the necessity of locating an airport close to the business center. This undoubtedly is true. However, not only is the element of time important, but the cost of additional transportation as well. Studies in some places have emphasized the fact that the cost of the additional hauling for mail, express, and passengers, over a distance of 10 miles as compared to 2 miles, may approach the amount of interest on the additional money which would be needed to purchase and develop a field near the center of the city. Commercial aviation perhaps has not yet reached the point, in this country at least, which would economically justify the clearing of a built-up area in the city for an airport. Nevertheless, such conditions may be anticipated with the perfection of helicopters, just as it has been found necessary in the past in the rebuilding or relocation of railroad terminals.

The City of Pittsburgh has some unusual problems in the development of an airport—because of topography and the difficulties of making a field rela-

tively level—but when these have been solved it will have some peculiar advantages because the field will be high in the air and will overlook most of the surrounding country. This elevation is important in regard to the question of fog and smoke; it also makes it possible to provide sufficient graded land, adjacent to the field, so that the parking of automobiles and the erection of shops and convenience buildings can take place without infringement on the clearance adjacent to the field. In other words, because of the resultant lower elevation for such purposes, there is no necessity for removing structures, or for parking cars, seven times their height horizontally from the field; or, as an alternative, decreasing the effective area of the available space by this amount.

Referring to the requirements of ample land area for future growth, it is notable that no mention is made of that for the parking of automobiles. This is an important necessity and there should be ample provision on four sides of the field, so that at times of great public demonstration cars may enter and leave the parking area without interference with other traffic. It is well to emphasize this need of provision for ample area, at least for later expansion, if required. The probabilities are in favor of additional land being needed for industries associated with air transportation, and for similar purposes. Aside from every other consideration, there is one convincing thought which gives assurance as to the probability of providing too large an area in view of anticipated improvements in airplane design. In the history of cities in the United States there have been few, if any, instances where too large an area has been set aside for public use.

One more item to which it seems desirable to call attention is that of the provisions for seaplanes. While this is an important matter for sea-coast towns, and those along the Great Lakes, it does not give the impression of being important for inland cities, even though they may have a good river harbor. The infrequency of such travel (due to the fact that most inland cities must utilize other forms of airships and that the interference of bridges is likely to be troublesome) does not suggest that much weight need be given to this element.

GEORGE D. BURR,[6] ASSOC. M. AM. SOC. C. E.—The subject of the proper location of airports is a timely one. It is perhaps too early to attempt to assign definite values or weights to the factors that must be taken into consideration in the intelligent selection of an airport site.

There is only one thing that commercial air transportation has to sell and that is speed, or time saving. The one factor on which the sale of this commodity hinges is safety and certainty of arrival on time. Therefore, a commercial or municipal terminal airport must be located as close to the metropolitan center of the city as safety will permit.

This rule is quite simply stated and quite difficult to apply. However, with existing commercial types of heavier-than-air craft, no site will be satisfactory regardless of other conditions: (1) If meteorological conditions are unsafe; (2) if the site is too small for safe landings or take-offs; (3) if

[6] Associate Engr., U. S. Dept. of the Interior, National Park Service, San Francisco, Calif.

dangerous flying practices are permitted over, on, or near the field; or (4) if the field is a long-time distance from the ultimate termination of the journey of passengers or commodities.

The cost of purchasing land, bringing utilities to the site, developing transportation facilities, improving difficult drainage, surfacing runways, leveling land, and similar factors, might be grouped under one single head, namely, cost of site.

If the nearest safe site that may be developed economically is a relatively great distance from the ultimate destination of passengers traveling to the city served it might be used, but always with the thought in mind that, although it is an aid to air navigation, another site, closer to the final destination, will some day be demanded when air transportation has developed sufficiently to make such more expensive sites economically feasible. However, if a site is close in, but is decidedly unsafe, because of meteorological conditions or small area, that site will be abandoned in the future.

These considerations would leave only three items to be considered in the selection of a terminal airport as follows:

| Factor. | Weight. |
|---|---|
| (*a*) Safety, with consideration of fog, smoke, wind, turbulence of air, and safe area of field | Mandatory. |
| (*b*) Distance from ultimate destination | As close as feasible in consideration of safety. |
| (*c*) Cost | Select the site that is cheapest to develop if two or more sites present the same relative advantages from the point of view of Factors (*a*) and (*b*). |

It must be borne in mind, however, that these remarks appertain to the selection of a terminal commercial or municipal airport for heavier-than-air craft only. There are many more classes of airplane landing fields to which these principles will not apply. For instance, there are: (1) Emergency and intermediate fields placed along an airway; (2) fields developed for the sole purpose of providing a training place for students; (3) fields located primarily as a junction and transfer point for air mail lines with little local delivery; (4) fields used principally for some specific commercial purpose, such as for tests by an airplane manufacturer, or as a terminal point for an air mapping company, or an air "taxi" or "joy hop" recreation center; and (5) fields devoted almost exclusively to the storage of privately owned craft used for private business or pleasure. The present tendency is to specialize in the use to which a field is to be put.

The question of just what amount of money may be justifiably expended on a given site by a given community or commercial enterprise is a matter for definite analysis. Eventually, the airport must pay a return on the capital invested.

There are several sources of revenue from a publicly owned airport enterprise. These are rental of hangar space; rental of concessions, such as restaurants, gas stations, etc.; rental of office space; charges for use of special facilities; and charges for landings. At present, charges for landings are seldom imposed, in order that flying may be encouraged. Hangar rentals and office rentals form the principal, immediately available, source of revenue.

A charge of 3½ cents per sq. ft. per month, and sometimes more, for hangar space is now quite generally imposed. Hangar space may be constructed for approximately $2.50 per sq. ft., including all costs, exclusive of land. If such hangars bring a return of 2½ cents per sq. ft. per month, an adequate return is made to amortize the investment in the structure within a reasonable time, and to pay interest, repair, and depreciation charges. The remaining 1 cent per sq. ft. per month of return may go to help pay field operating expenses, maintenance, and purchase cost of land. This specific feature has been elaborated somewhat in order to show the nature of the financial problem.

N. H. ANGELL,[7] ESQ.—In this paper a rating of 14 points was given to the physical features of the airport. The factors which would influence the percentage of rating under this classification would evidently be the condition of the surface of the field, and the manner in which the field is laid out. The latter has been well covered in *Bulletins* of the U. S. Department of Commerce and by the author.

The question of surfacing has usually been left to the individual fields to work out for themselves. It is a question of special interest on the Pacific Coast. There is no doubt that some kind of a surfacing is necessary. Due to the lack of rainfall in summer months and the consequent cost of irrigation, turf fields have been virtually prohibited in the Far West. The development of some other type has been necessary.

Aside from the question of elimination of dust, the functions most desired in runway treatment are that it shall provide a firm surface over which planes can accelerate to the desired flying speed in the shortest distance, and that this be done with comfort to passengers at all times when weather permits flying. With the flying speed of planes ranging between 50 and 75 miles per hour, the take-off can be made in a shorter distance when the run is over a firm, even surface than when it is attempted from a rough, irregular, and perhaps muddy field.

Increased passenger carrying is demanding surfaced fields. In the larger airports constructed by aviation corporations which have sufficient money available, the surfacing of the field is one of the major items considered, and in many cases the field is not opened until such surfacing has been completed.

The use of hard surfaces on landing areas is not regarded with favor by most pilots. A comparatively soft, resilient surface is preferred, one that will have an appreciable tractive resistance and aid in slowing down the plane, as well as help to absorb the shock of impact. The drag of a tail-skid on a surface of the proper consistency aids materially in decreasing the run after land-

[7] San Francisco, Calif.

ing, although its primary function after the plane is on the ground is to exert a stabilizing effect and eliminate any tendency of the plane to veer from one side to the other or "ground loop." In order to insure this desired stabilizing effect, a somewhat soft or plastic landing surface is preferred. Properly constructed, this surface is also suitable for take-offs.

Asphaltic oils with a properly graded sand have been used for the construction of such surfaces. The treatment may consist of a surface application in which the oil is allowed to penetrate, or if more money is available, analysis of the soil may be made and, with the addition of foreign sand to supply any deficiency in the grading of the natural soil of the airport, an oiled sand mat may be built up by successive applications of oil, each application being mixed with the sand by harrowing and blading. This is similar to the "mixed-in-place" method used in the construction of secondary highways in many of the States, except that the grading of the aggregate is quite different. When practical, it is preferable to mix the surface in an asphalt plant in much the same manner as the ordinary asphaltic concrete or sheet asphalt types of surfacing are mixed. This provides for an accurate control of the aggregate and oil at all times, insuring uniformity of the surface.

On the United Airport at Burbank, near Los Angeles, Calif., there are approximately 70 acres of runway surface treated with a pre-mixed oiled sand material. For this work the aggregate was in some cases as large as ½ in., grading down to 200-mesh material. There are three runways on this airport, each 300 ft. wide and averaging 3 500 ft. in length. The plant-mixed asphaltic surface is soft enough to be marked and even creased by tail-skids, but firm enough for take-offs under all weather conditions encountered. In addition, there are about 50 000 sq. yd. of asphaltic concrete, 4 in. and 3 in. in thickness, on roadways, warming-up platforms, and parking areas.

There are a great many airports in California that have oil-treated surfaces and the dust nuisance has thus been largely eliminated. Such treatment has resulted in increased revenue from passenger carrying and decreased maintenance costs on the airport surfaces and on equipment operated from the field.

Many fields have started in their surfacing program by paving the areas adjacent to the hangars, such as the aprons and warming-up platforms. The pavement has been made as thin as possible, consistent with the subgrade and the load to which it will be subjected. By using a minimum thickness, larger paved areas are possible from the same funds. It is felt that if there is an increase in the size of planes to such an extent that the pavement will not be strong enough, bituminous types can be easily thickened by a resurfacing course, without sacrificing the initial investment.

J. OGDEN MARSH,[8] M. AM. SOC. C. E.—When automobiles first began to appear, most people regarded them as a "rich man's toy", and not until the public took them seriously and as a commonplace part of daily life did the automobile industry begin to grow. The present state of the public mind in regard to aeronautics is somewhat similar, and in the speaker's opinion,

[8] Chf. Engr. and Gen. Mgr., Board of Public Utilities and Transportation, Los Angeles, Calif.

there is nothing more important than to have the public become so familiar with airplanes that they will look upon them as ordinary functions of daily life.

The author has stressed the necessity of public support for the acquisition and construction of principal airports. The public does not expect steamship companies to pay for harbor development, and they probably should not expect air transportation to provide the airports. If aviation interests are to have public support financially, they must make the public "air-minded".

As airplane activities must naturally be centered about airports, the problem resolves itself into one of getting the public to take more interest in visiting airports, both public and private, and in actually seeing the operation of flying. To accomplish this, planning engineers must make airports not only extremely accessible, but they must make them attractive. There must be correlated with airports, and their surroundings, other and more familiar lines of interest and amusement that will bring people to these localities. This is a matter which should be given some thought, because it is important to get the crowds there. To do this with convenience, the necessary roads must be built for motor vehicles.

The desire, however, to attract crowds should prevent the absolute prohibition of stunt flying, as such flying fosters the public belief that airplanes are not a safe and dependable means of transportation.

ARCHER R. NORCROSS,[9] ASSOC. M. AM. SOC. C. E.—The author mentions the layout and construction of runways and gives several types of surfaces which have been advocated for runway construction, or have been already used on some airports. The proper surfacing of the airport is a problem which is being given constantly increasing attention and thought on the part of airport designers and constructors. While the surfacing must provide for an entirely new type of traffic, the methods used by highway engineers, and the lessons which they have learned in the development of durable and economical surfaces, may be well applied to airport work.

Runway surfaces must be firm enough to resist displacement under loads which are already up to 25 tons and may become greater. They must be free from any tendency to rut or break. In addition to the static load which they must stand, the force of impact must be considered. It would thus appear that the surfacing material should be of a type which is easily thickened to take care of the increased loading that may be expected as a result of the tendency for planes to develop along a larger scale.

The methods of the highway engineer as exemplified on the new construction work on secondary roads in the West may well be adapted to preliminary construction on runways. The application of an asphaltic oil with surfacing of fine screenings and the whole compacted by rolling so that a water-proof and firm surface is obtained, or some similar method of treatment, will not only provide a runway surface that will serve for some time, but it assures an excellent sub-grade for future paving.

[9] Brookline, Mass.

There is one item which enters into the construction of airport surfaces with much more importance than is attached to it in highway work, that is, the visibility of the surface. Oiled or dark bituminous surfaces appear to be regarded with most favor by pilots. It might be of interest to note here that at the request of pilots, all light-colored roadway surfaces in the vicinity of the North Island Naval Air Station, at San Diego, Calif., have been given a color coat of dark material.

The question of visibility at night is entirely one of adequate lighting. Wide markings on dark-colored pavements, or the outlining of such pavements in white, in conjunction with proper lighting equipment, would appear to provide the best visibility both for day and night flying.

A resilient surface aids materially in absorbing sound and impact, both of which are important considerations for airports. With these ideas in mind, it is not difficult to appreciate the trend toward the bituminous type of surfaces on the Pacific Coast.

JOHN NOLEN,[10] M. AM. SOC. C. E. (by letter).—In discussing this paper the writer would like to emphasize some of the points mentioned by Mr. Baker, but which owing to the broad scope of the subject had to be limited in consideration. These points are those having city planning relationship. As an outstanding feature of modern transportation the airport has an effect upon the city or urban community as a unit. To choose a site without consideration of all the elements of the community composition may mean that either the city may be injured by the location given over to the airport, or, in turn, the airport may not be so situated as to serve the city economically; or still worse, it may be so placed that it cannot develop business either from the city or serve as an adequate and safe stopping point on an airway for traffic from outside.

In these days American cities and communities of various types have come to a fairly complete comprehension of what city planning means. They have arrived at this comprehension through two channels: (*a*) The necessity of looking after the physical side of the city to meet the ever-increasing congestion due to the increased measure of transportation facilities, the growing density of population, and the recognized need for wider means of recreation; and (*b*) the increasing financial complications and problems that are thrust upon it by unplanned and misguided or wasteful developments of the past and present.

As a consequence of the growing population and this understanding of urban complications, the duly constituted authorities are preparing comprehensive plans to guide and control the various improvement activities of the city for the general welfare. These may be considered under three subdivisions, as follows:

(1) Thoroughfare plans which after careful study are prepared to designate the thoroughfare system and routes for the various classes of traffic; the most appropriate and economical widths of streets and pavements; the

[10] City Planner, Cambridge, Mass.

ways and means of effecting grade separations at conflicting traffic intersections; and related problems.

(2) Zone plans which divide the city into districts or groups of districts of like land use, so as to provide better for the general welfare and orderly growth of business, industry, and residence, and to secure permanence in the investment in land and buildings, and promote general welfare and public safety.

(3) Plans for parks and open spaces to secure the much needed recreational facilities for the present generation and provide for the future needs, as well as the acquisition and development of land to preserve features of natural scenic beauty and historic interest.

It is through these plans and their co-ordination as comprehensive planning for the future that provision should be made for the location of an airport, and no airport site should be selected without reference to these important controlling factors.

*Influence of the Thoroughfare System on the Airport Site.*—The outstanding contribution of aviation to modern transport is that of conservation of time, which Mr. Baker has rated as about 66⅔% saving for distances of 500 miles, or more, with a reduced advantage for shorter hauls. It is highly important, therefore, that the tremendous advantage in time saving be not diminished or lost through inadequate facilities on the ground between the airport and the points throughout the city or region from which air traffic will originate. It is the function of the thoroughfare plan to provide the best means of getting quickly and safely from one point in the community to another by creating direct routes, easy grades, and adequate width of pavement; by eliminating obstacles, such as railroad-grade crossings and highly congested street intersections; by the orderly control of traffic flow on highways; and by the provision of equally well-organized transit facilities.

*Recognition of the Principle of Distribution of Land Uses, or Zoning in Relation to Airport Sites.*—An early recognition that airport location is one of the established land uses, such as business, industry, or residence, and that it is not an isolated item, will aid materially in locating the airport on a site where it may become a permanent asset to the community. To locate a use outside its proper zoning district makes of it a non-conforming use, injurious to the welfare of its neighbors and subject to many restrictions on expansion and development. The general terminal airport is an activity displaying characteristics which, in their preponderance, will eventually classify it as an industrial activity. It must provide storage in quite large proportions; it transacts business during the day and more and more in the future will do business at night; it has adjacent manufacturing, or perhaps will have manufacturing, facilities for ships or parts; it must provide repair facilities; and, in its fundamentals, it must combine the facilities of business and industrial uses. Specialized airports, of course, may be appropriate for residential districts, where the chief function is the embarking or debarking of passengers. In general, however, the airport is an industrial establishment and should seek its location in an industrial district. The related question of airways is important, and some of the principles involved in the selection

of an airport should govern in the location of the airway over a community. As pointed out in the paper, it is important that the airport be so located as to reduce the actual flying over built-up sections and especially the residential areas.

*Relationship of Recreational Facilities to Airports.*—By appropriate design and co-ordination between the various agencies of the community government, the airport can be made a part of the recreational system of a community without in any way impairing its technical or operating efficiency.

The fundamental element in an airport is the landing field, about which are grouped other elements required for the complete functioning as a transportation agency. This landing field is an open space contrasting quite strikingly with the adjacent appendages. The airport in this open-space respect again contrasts with the built-up areas of the community, which, of course, vary in degree of density. It is, in part, this open area as one of the breathing spaces which makes it desirable to co-ordinate with the recreational system.

In addition to the benefit of the open space to the community, wherein there is free movement of air, there is always the value of the whole airport as an out-of-doors place of stimulating interest and activity, where imagination may be stirred and people aroused from routine ways by seeing and being associated with this modern system of transportation.

By skillful design the airport may be made a place of pleasure and amusement as a third form of recreational activity. Already one of the active pursuits in most airports is the sight-seeing trip which gives the visitor an opportunity to make his first flight or to cultivate a form of recreation for which a liking has already been established. Additional facilities for recreation would be established by the introduction of suitable restaurants, hotels, and allied places of amusement or sports.

Air transportation is making its way, and the city which does not adopt and plan measures for the airport will find itself in a few years left far behind in the relentless march of modern achievements.

S. N. GRIMM,[11] ASSOC. M. AM. SOC. C. E. (by letter).—The spectacular developments in design of large airships, both heavier and lighter than air, bring, as a result, a pronounced differentiation of air traffic. While the large airships tend to serve the same purposes as ground and sea common carriers, the smaller aircraft confine themselves more and more to functions similar to those of the automobile and motor-boat.

As time goes on great planes and dirigibles will be used for long-distance transportation along the principal routes of travel, with a limited number of stops, while the smaller planes will mostly fly comparatively short distances between the airports of a section of the country.

Many landing fields will serve exclusively the purposes of small aircraft, forming air highways, as it were. According to the data of the U. S. Department of Commerce, on July 1, 1929, there were 305 approved types of planes, 267, or 87%, of them having capacities of from one to six places. It is impos-

[11] Syracuse, N. Y.

sible to predict what will happen to this ratio in the future, but it is safe to assume that small aircraft will increase more rapidly in number than large airships. It is also evident that the future of private flying depends upon the improvement in design and in manufacturing of smaller planes, affecting their efficiency and cost, as much as upon the growth of the number of landing fields convenient for the purposes of private flying.

The problem of locating such fields to be used by private planes for landing, storing, and minor repairs only, may be solved in the manner suggested by the author for major airports. However, the factors should be given different weights, according to the special purpose of the fields, the following being an example rather than suggestion:

| Factors. | Weight. |
|---|---|
| (*a*) Topography | 10 |
| (*b*) Physical features | 12 |
| (*c*) Meteorology | 12 |
| (*d*) Location with respect to community served | 5 |
| (*e*) Transportation facilities | 11 |
| (*f*) Accessibility | 25 |
| (*g*) Legislative control | 2 |
| (*h*) Utilities available near site | 3 |
| (*i*) Cost | 10 |
| (*j*) Miscellaneous | 10 |
| Total | 100 |

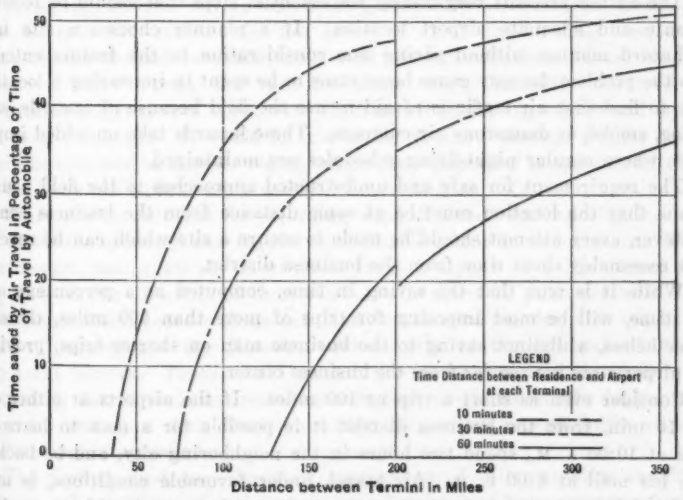

FIG. 3.—SAVING IN TIME ACCOMPLISHED THROUGH USE OF PRIVATE AIRPLANE INSTEAD OF AUTOMOBILE.

The weight of 25 points is given to the factor of accessibility of secondary airports, while the author gives to the same factor only 11 points for major airports. The reason for such a difference lies in the fact that, while the heavy

air transport gains in its efficiency over ground common carriers in very long flights, the lighter air transport has to find its justification in an efficiency superior to that of highway travel in comparatively short distances.

Fig. 3, which is plotted in a manner similar to Fig. 2, shows a marked decrease in rates of time saved through the use of an airplane, instead of an automobile, due to remote location of airports, for distances up to 360 miles. The following assumptions are made in this connection:

| | |
|---|---|
| Airplane speed, in miles per hour | 80 |
| Automobile speed, in miles per hour | 33 |
| Time allowed, in minutes, for getting a plane ready and placing it in the hangar | 15 |
| Time allowed, in minutes, for stop-over of plane and automobile after 200 miles | 30 |
| Time allowed, in hours, for stop-over of plane and automobile after more than 200 miles | 10 |
| Limit of distance traveled, in miles per day, by automobile | 360 |

The author is certainly right in his assertion that owners of private planes would not care to spend an hour traveling to the airport for a flight of like duration.

R. U. St. John,[12] Assoc. M. Am. Soc. C. E. (by letter).—The importance of applying sound engineering practice to the location of airports cannot be emphasized too strongly at the present time, when so many cities are contemplating such development.

The author presents very clearly the essential steps that should be followed in safe and adequate airport location. If a planner chooses a site in a haphazard manner without giving due consideration to the factors entering into the problem, he may cause large sums to be spent in improving a location, only to find that air traffic is afraid to use the field because of hazards, such as fog, smoke, or dangerous air currents. These hazards take on added importance where regular night-flying schedules are maintained.

The requirement for safe and unobstructed approaches to the field usually means that the location must be at some distance from the business center. However, every attempt should be made to secure a site which can be reached in a reasonably short time from the business district.

While it is true that the saving in time, computed as a percentage over rail time, will be most imposing for trips of more than 500 miles, there is, nevertheless, a distinct saving to the business man on shorter trips, provided the airports are not too far from the business center.

Consider even as short a trip as 100 miles. If the airports at either end are 15 min. from the business district it is possible for a man to leave his desk at 10:00 A. M., spend two hours in the neighboring city, and be back to sign his mail at 4:00 P. M. Air travel, under favorable conditions, is more restful than any other means of transportation and a man would return from such a trip without feeling fatigued. To make the same trip by rail or automobile would take the business man away from his desk at least eight hours and he would return tired and travel-worn. The saving of travel time, com-

[12] Mgr., San Francisco Bay Airdrome, Alameda, Calif.

puted as a percentage, may not be great, but the saving of business hours is of real value.

The study of meteorological conditions is of extreme importance in airport location. No one would think of building dock facilities for large boats drawing 30 ft. of water without first determining, by soundings, that the harbor would handle craft of that draft. Many communities, on the other hand, proceed with airport development, at considerable expense, without adequate data on wind direction and velocity.

The two most important meteorological factors from the aviator's standpoint are fog and wind direction and velocity. There is a real need for simple and inexpensive instruments that will record these data. If such instruments were available they could be installed for a period of six months or a year at proposed locations and would thus furnish the information accurately. They would be particularly valuable to smaller communities that do not have Weather Bureau Stations.

So far as the writer knows, there is no way of recording the actual presence of fog accurately other than by visual observation. In a recent study, the Airport Commission of the City of Sacramento, Calif., made use of recording hygro-thermographs in order to obtain data on fog conditions. These instruments were set up at representative stations throughout the area being studied. They furnished a continuous record of humidity and temperature during the three months' period when fogs occur in the region of Sacramento. By using the percentage of time during which 100% humidity was recorded, it was possible to rate the stations in the order of their fog-forming tendencies. These results seemed to check fairly well with simultaneous visual observations; in other words, the stations where 100% humidity occurred for the greater proportion of time, were those at which the fog was most frequent and most persistent. It would be interesting to know whether similar results would be obtained in another region where the topography is uneven and where the fog belts are more sharply defined.

There are instruments for recording wind direction and velocity, but they are expensive to install and require considerable attention to maintain. These instruments record all air movements from a zephyr to a hurricane. For airport work the direction of light winds, up to about 10 miles per hour, is of little importance, because ships can land "cross wind" under such conditions without hazard; but the direction and velocity of the stronger winds are important factors. There would seem to be no serious mechanical difficulty in turning out an inexpensive instrument that would record the higher wind velocities and show their direction within 10°, which is sufficiently accurate for locating runways.

The factors used as a basis of comparison of different sites should be definite and specific so that their value can be obtained by computation, as far as possible. The choice of a municipal airport location is a problem that usually interests real estate men with property to sell. If the factors used in determining the comparative merit of the different sites are assigned values on the basis of judgment alone there is opportunity for endless discussion

and a danger perhaps of setting aside the recommendation of the body making the report. On the other hand, if the majority of rating factors are computed there is little room for argument.

As an example of a set of rating factors, most of which can be computed, Table 2 is taken from the report of the Airport Commission of the City of Sacramento.

TABLE 2.—Relative Weight of Factors Involved in Choosing the Location of an Airport at Sacramento, Calif.

| Item No. (1) | Subject. (2) | Rating factors, ideal site. (3) | Rating factors, site selected. (4) |
|---|---|---|---|
| 1 | Freedom from dense river fogs | 15 | 12.3 |
| 2 | Freedom from bad air currents | 10 | 8.0 |
| 3 | Area of field | 10 | 9.2 |
| 4 | Configuration of field | 5 | 5.0 |
| 5 | Approaches, satisfactory areas under take-off | 8 | 8.0 |
| 6 | Favorable prevailing winds relative to runways | 5 | 3.0 |
| 7 | Prospective neighborhood development | 4 | 3.0 |
| 8 | Possibility of expansion | 4 | 4.0 |
| 9 | Location relative to axis of air travel | 10 | 6.0 |
| 10 | Distance from post-office | 10 | 5.0 |
| 11 | Distance from population center | 10 | 6.3 |
| 12 | Distance from railroad | 4 | 2.0 |
| 13 | Distance from airplane factory sites | 5 | 2.0 |
| | Total | 100 | 73.8 |

This Commission spent nearly a year studying twelve proposed sites on a basis similar to that which the author of this paper advocates and was successful in securing the adoption of its report. The Sacramento Municipal Airport is now being constructed on the site recommended.

After assigning factors for the ideal site, the next step was to assign the proper values to each rating item for the various sites under consideration. The total of these values for any field would be its rating factor (see Column (4), Table 2). The assignment of the values was made by computation as far as possible, although a few of the items were necessarily matters of judgment only.

*1.—Freedom from Dense River Fogs.*—The meteorological survey gave the information from which values of Item No. 1 were obtained. The four meteorological stations were rated in the order of their freedom from fog conditions, and this information was applied to the sites in the region adjacent to each station.

*2.—Freedom from Bad Air Currents.*—Values of Item No. 2 were matters of judgment and were assigned after numerous flights over the sites to determine the presence of any unusual air conditions. The proximity of trees or buildings causes uneven air currents and this fact was also used in determining this factor.

*3.—Area of Field.*—It was decided that an area of 250 acres represents the ideal site because it would give all the space needed at present and allow for a

moderate expansion program. Sites larger or smaller than this ideal size were penalized in proportion. For example, the rating factor for a 400-acre tract would be $10 \times \frac{250}{400} = 6.25$.

*4.—Configuration of Field.*—The factor assigned to Item No. 4 was largely a matter of judgment. A rectangular field at least 2 500 ft. wide, with its length in the direction of the prevailing winds, would be the ideal shape. Odd-shaped fields on which it was difficult to lay out proper runways were penalized.

*5.—Approaches, Satisfactory Areas Under Take-Off.*—The total length of runways in the north and south and northwest and southeast directions was used as the basis for rating Item No. 5. If these lengths totaled 8 000 ft., the site received a full rating of 5. Shorter lengths were reduced in proportion.

*7.—Prospective Neighborhood Development.*—Factors for Item No. 7 were matters of judgment. If the trend was toward commercial or residential building, a low rating was given, as this type of development close to an airport is hazardous. If the trend was only agricultural development, a high rating was given.

*8.—Possibility of Expansion.*—If all four sides of a tract were open to expansion, the full rating of 4 was given. If one side was blocked by a railroad or similar obstacle, the rating would be 3, etc.

*9.—Location Relative to Axis of Air Travel.*—Item No. 9 was appraised largely on the basis of judgment and conjecture as to future lines of air travel. In general, sites to the east of the town received the higher ratings because they are nearer the San Francisco-Reno Air Line.

*10.—Distance from Post Office.*—For any field, the rating for Item No. 10 was determined by the formula:

$$P = 10 - d \qquad (1)$$

in which, $P$ is the rating factor, and $d$ is the distance, in miles, to the nearest post office. Ten was used as a limiting factor because it was felt that a site more than ten miles from the Post Office would have no value as an air mail field when so many closer sites are available.

*11.—Distance from Population Center.*—The value for Item No. 11 was computed the same as that for Item No. 10.

*12.—Distance from Railroad.*—Sites more than a mile from a railroad received zero rating. Those less than a mile were rated in proportion, the one having full rail connections adjoining the property receiving a full rating of 4.

*13.—Distance from Airplane Factory Sites.*—In general, Item No. 13 is affected by the same factors as Item No. 12, but special recognition was given to sites that had particularly good factory locations adjoining.

The data finally to be considered by the Commission consisted of the estimated cost of improving each one of the twelve proposed sites and a rating factor that indicated the value of the site as an airport. The last step was to divide the total estimated cost for each site by its rating factor to get a unit rating cost. This indicates the site which has the lowest cost per unit

of rating and is a valuable indication of the best site from the standpoint of both rating value and cost.

It is hoped that one result of this paper will be to establish the general principles of airport location and to pave the way for a uniform rating schedule that will facilitate the comparison of proposed sites as well as completed airports.

JOHN F. PARTRIDGE,[13] M. AM. SOC. C. E. (by letter).—The writer wishes to offer two suggestions which might be overlooked amid the many factors that will confront location engineers on airport developments.

The location of the airport for the small town should be made in the interests of the through transportation of mail, express, or passengers. The volume of business having the small town as its terminus is generally small by comparison, and time saving between the larger centers is the prime consideration. The smaller center will generously concede priority of convenience for the privilege of a tie to its larger neighbor. Transportation between the individual smaller centers on the route of flight is a result of convenience generally due to a scarcity of other available means of transport, and airport location should be again made in the interests of through service, either present, or possibly in the future. Utter disregard, by through service, of the demands of the smaller communities, however, is not in the best interests of air transportation. The cultivation of public interest in aviation in the smaller town will result in increased air travel with its inevitable concentration around the larger communities.

Airport location in mountainous country should include consideration of the angle of slope from the tops of the neighboring mountains into and from the landing field. For smaller towns where through-transport planes stop for refueling, or the picking up of mail or passengers, it should be remembered that circuitous climbing to gain the necessary elevation to cross the mountains, may consume a considerable part of the total time between terminals. For larger centers, while this question of time lost in gaining altitude is still an important consideration, the other factors usually peculiar to a proper location of the airport may have to take precedence.

WILLIAM J. FOX,[14] ASSOC. M. AM. SOC. C. E. (by letter).—Air transportation has so fixed itself into the modern method of traveling that it is now an established economic necessity.

The time element factor which differentiates the automobile from the airplane is so great that, economically, the business man can no longer afford to travel long distances by automobile. The time element in modern business is of such importance that this one factor alone determines the success or failure of the business structure. To no small degree has this same element entered into present-day social and recreational existence.

The fact that transportation is necessary at all is, basically, a handicap to any business. As an example, two businesses of identical character, one requiring transportation facilities for its operation and the other so located

[13] Hydr. Engr., Emprezas Electricas Brazileiras, S. A., Rio de Janeiro, Brazil.
[14] Chf. Engr., Los Angeles County Regional Planning Comm., Los Angeles, Calif.

as to not require such facilities, other things being equal, it will be found that the transportation factor determines, in terms of time and cost, the financial differential of the two enterprises. Therefore, the form of transportation which minimizes most successfully the time element, with a corresponding reduction of cost, and which more closely approximates the condition in which no transportation is necessary, is of the greatest economic value. Aviation or air transportation is and no doubt always will be the most effective in meeting the foregoing requirements.

*Safety in Aviation.*—Taken in relation to certain facts, the present mortality arising from air travel is surprisingly small. The vital statistics of the United States, England, and Wales indicate that the number of deaths in aviation per 1 000 000 of population is quite uniform.

The airplane, in the main, has gone through the throes of the experimental stage in so far as structural characteristics are concerned. Airplane motors have been perfected to the same degree as the most finely finished watch. Accidents due to structural defects are an extreme rarity. Only 5% of the total number is due to this cause. The fact seems to be that passengers, on regular air lines owning perfect machines that are under the control of regularly licensed pilots, enjoy a good degree of safety.

The airplane undoubtedly has achieved the highest place as a medium for transportation, especially for long distances. The financial advantage of utilizing this form of transportation for both passengers and light cargoes is strongly manifested by the air transportation companies that have been formed during the past few years and by the tremendous amount of capital being invested in the aviation industry.

TABLE 3.—Comparative Mortality in Air Travel.

| | Year. | Mileage. | Fatalities. | Average per 1 000 000 population. |
|---|---|---|---|---|
| United States | 1926 | ..... | 160 | 1.5 |
| United States | 1927 | ..... | 214 | 1.6 |
| United States (first six months) | 1928 | ..... | 161 | 1.6 |
| British Air Lines | 1925–1927 | 2 471 000 | None | ... |
| British Air Lines | 1922–1924 | 2 596 000 | 15 | 1.4 |
| Luft Hansa, European | 1925–1927 | 12 605 000 | 22 | 1.7 |
| United States | 1921–1926 | ..... | 908 | 1.5 |
| England and Wales | 1921–1926 | ..... | 265 | 1.1 |

The success of the airplane as a safe and efficient means of transportation is largely dependent upon the selection and design of the airport on which it must land and take off. Airport location looms as one of the chief factors involving safety as well as the future development of aviation. The present airports in American cities in general, even those of the largest size, are being adjudged as inadequate and inefficient.

*Selection of Modern Airports.*—To gain public confidence in this form of transportation, airport sites must be selected on the basis of engineering judgment coupled with the advice of flying experts. They should be laid out to the best advantage, with the aid of engineering skill.

If aviation is to grow as it has a right to grow, it must enlist the services of the flyer himself, the civil engineer, the architect, and the city planner, as it has enlisted the services of the scientists, the navigator, and the motor expert.

One or two serious accidents to passenger planes, due to the unwise selection or faulty design of an airport, has a disastrous effect upon the aviation industry as a whole. The right to fly air mail over a community might even be put in jeopardy. In view of the position that aviation now holds in the economic structure of the United States, it is essential that public confidence should be augmented rather than impaired.

The selection of a field is more than a real estate transaction. Competent men who are engaged in the actual flying of aircraft should be consulted in order that the particular field under study be given the official endorsement of those men who will be called upon to fly planes to and from the airport when selected.

*Technical Advice.*—Mr. Baker emphasizes the importance of certain factors in determining the proper location of airports. It is imperative that factors be used which will tend to give an impartial rating by a purely mathematical or mechanical process. These factors should be a minimum in number, but at the same time representative of the vital characteristics of a safe and efficient airport. Quite as important as the factors themselves is the procedure followed in leading up to their application, for example: (*a*) Survey of the area to be served; (*b*) technical advice; (*c*) future predictions of population and airplane growths; (*d*) economic analyses; and (*e*) application of factors by qualified experts.

The lack of technical advice is not only expensive in the initial selection of the field, but poor judgment in the selection as to proper location usually entails great cost in order to modify conditions to make the airport safe and adequate. The cost of adjusting topographical conditions, the elimination of hazards, and the installation of drainage systems on a poorly selected field runs up the cost to such an extent that it might have been more profitable to have selected a site, the initial cost of which was far greater. Likewise, the adequate laying out of the development plan for an airport is, in many respects, similar to planning a small city.

The matter of controlling the height of buildings constitutes a strong factor. Height limit regulations in the vicinity of a field give the operators assurance that they will have the best possible use of their field; they also contribute added safety to those using the air as a means of transportation.

*Selection with Respect to Growth Trends.*—Airport selection and construction require a careful study of land areas, growing and shifting population, industrial and residential development.

The selection of an airport site is properly a part of city planning, and as such should be in conformity with the future development program. As part of its planning activities, every city should prepare an airport development program that will provide for future needs on the basis of real economy.

The airport is the gateway to the modern city. If properly selected, a satisfactory financial return can be shown for the investment involved. To

make the investment economically sound, however, the following principles must be rigidly adhered to:

1.—The site should be selected by qualified experts.
2.—The land should be owned in fee or on long-term lease.
3.—The airport should be accessible to those served by a maximum of 20 min. surface transportation time.
4.—The field should be of the highest rating conmensurate with use.
5.—Proper legislative control should be enforced over surrounding development.
6.—The field should be properly related to the community served and other fields.

*Los Angeles County Method of Locating Airports.*—In the latter part of 1927 Los Angeles County made the study of airports, landing fields, and various ground requirements a part of the activities of the Regional Planning Commission. This Commission is a part of the County Government and is charged with the duty of planning the wholesome development of the County as one great commonwealth. The area involved was slightly less than 5 000 sq. miles, including forty-four incorporated cities and thirty-six unincorporated towns. It was obvious that thorough planning had to embrace the requirements for this new form of transportation. Otherwise, any shortcomings would be discovered too late to adjust the development economically to the situation.

*Population and Airplane Density.*—Fig. 4 shows the increase in the number of airplanes in Los Angeles County, California. It likewise shows the growth of population for a considerable period. Both these growth curves are projected into the future for a 30-year period. From the resultant quantities of these two curves, a third curve is plotted, called "The Airplane Density Curve", which represents the number of persons per airplane as of the past and as anticipated in the future.

The present status in this County (1930) is 1 airplane to every 2 500 persons. It is estimated that by 1980 this ratio will be 500 persons per airplane, and in the year 2030, 100 persons per airplane.

With the population curve as the basis and the 20 min. of surface transportation as a maximum figure, some basic information is provided upon which to calculate the size and frequency of the airports that will be necessary to satisfy future needs.

Due to the very rapid growth experienced, it was evident that the improper location of one road might forever destroy a dominant site for a future airport or landing field. The time to locate airports is before land is subdivided or cut up by streets or highways. Therefore, a study of the requirements that would be needed for the future of aviation was made in conjunction with the plans and studies for highways, population densities and trends, industrial development, transportation facilities, zoning, and land subdivision. The results have been co-ordinated into a master plan. As divisions of the Master Plan are completed they are submitted for official and public approval. The entire procedure involves six steps, namely, (1) to take an inventory of existing conditions; (2) to form an aeronautical advisory committee; (3) to make a comprehensive study of available sites; (4) to estimate the cost of equipment and improvements for airport operation; (5) to analyze the financing and probable earning ability; and (6) to design the airport.

*Step No. 1.—Inventory of Existing Conditions.*—A survey and inventory were made of all existing airports, landing fields, and aviation facilities within the County. With respect to each existing airport information was obtained as to the following factors:

(1) Location.
(2) Description.
(3) Runways and landing areas.
(4) Obstructions and hazards.
(5) Equipment.
(6) Improvements.
(7) Conditions of ownership.
(8) Class.
(9) Area.
(10) Elevation.
(11) Drainage conditions.
(12) Soil conditions.
(13) Meteorological data.
(14) Transportation facilities.
(15) The name of the operator.

The survey revealed that there were fifty-two fields in operation. They were of all sizes, shapes, and conditions of ownership. The relative sizes were found to be as follows:

| Size, in acres. | No. |
|---|---|
| 20 to 30 | 15 |
| 30 to 50 | 6 |
| 50 to 100 | 7 |
| 100 to 160 | 7 |
| 250 | 1 |
| 380 | 1 |
| 640 | 1 |
| Not determined | 14 |
| Total | 52 |

The acreage was variously owned, as shown in Table 4.

TABLE 4.—Comparison Showing Nature of Ownership.

| Nature of ownership. | Number of acres. | Number of fields. |
|---|---|---|
| Public | 784 | 5 |
| Private | 570 | 8 |
| Leased | 227 | 39 |
| Not classified | 2 050 | .. |
| Total | 3 631 | 52 |

Many of the fields were operating on leases of from thirty days to ten years, as shown in the following list:

| Length of lease. | Number of airports. |
|---|---|
| 30 days | 20 |
| 60 days | 2 |
| 90 days | 3 |
| 1 year | 2 |
| 2 years | 1 |
| 3 years | 4 |
| 5 years | 4 |
| 10 years | 3 |
| Not leased | 13 |
| Total | 52 |

This short-term lease condition greatly handicaps the developers and operators in securing loans or encouraging investments for expansion or permanent improvements.

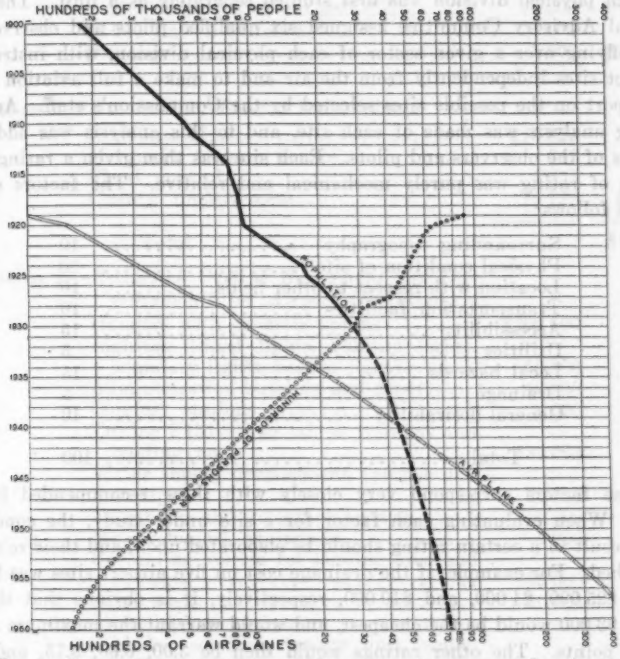

FIG. 4.—CURVES SHOWING INCREASE IN NUMBER OF AIRPLANES IN LOS ANGELES COUNTY, CALIFORNIA, AND GROWTH OF POPULATION.

*Step No. 2.—Formation of Aeronautical Advisory Committee.*—Although the Commission was equipped with a technical personnel of engineers, architects, landscape architects, and statisticians, it realized that it must be fortified with proper aeronautical advice to obtain a true cross-section of aviation problems and requirements. To meet this situation, an Aeronautical Advisory Committee composed of expert flyers from the Army and Navy, U. S. Department of Commerce, air transport companies, aerial police, and civilian flyers, was formed. The studies, designs, and accomplishments of the Commission were placed upon a basis as nearly scientific as possible.

*Step No. 3.—Comprehensive Planning of Airports.*—After all the existing fields had been surveyed, plotted on maps, and evaluated, the technical staff of the Commission divided the County, for the purpose of study, into the following natural physical divisions: (*a*) Antelope Valley; (*b*) San Gabriel Valley; (*c*) San Fernando Valley; (*d*) La Crescenta Valley; (*e*) the Central Area of Los Angeles; (*f*) Southeast Section; and (*g*) Pacific Coast Beach Section.

With the aid of maps showing the existing and proposed highway systems, other maps showing land that was subdivided, and with U. S. Geological

Survey maps showing topography (scale 1 in. = 2 000 ft., with 5-ft. contours), the technical staff indicated every flat parcel of land that had any possibilities whatsoever as a potential airport.

Each physical division was first studied separately as a unit. The Aeronautical Advisory Committee assigned six qualified pilots and observers the job of flying over a given sector of each physical division, with instructions to select sites independently from the air and to make a full aviation survey and report on the possible sites selected by the Commission's staff. An engineering analysis was made of each site, and to this analysis was added the findings of the observers and pilots. Each site was then given a rating. The process of rating was purely mechanical and relative. The factors applied were as follows:

| | |
|---|---|
| Surrounding topography | 10 |
| Physical condition of site[15] | 20 |
| Location with respect to other fields | 10 |
| Transportation facilities | 10 |
| Accessibility | 15 |
| Utilities | 5 |
| Local hazards | 15 |
| Drainage | 5 |
| General desirability | 10 |
| Total | 100 |

These factors correspond very closely with those recommended by Mr. Baker. When evaluating each factor for a site under study, the conditions which result in a certain rating should be elaborated upon, and their relativity established. For example, if the drainage cost on five airport sites was $3 000, $5 000, $25 000, $4 000, and $10 000, respectively, it is obvious that the one costing $3 000 would be the cheapest, and would warrant the maximum rating of 5.00 points. The other ratings would then be 3.00, 0.60, 3.75, and 1.50, respectively.

The engineering analysis of a site followed a procedure which analyzed the physical characteristics, cost of grading, drainage, flood protection, and removal of hazards, its relation to present and future population, its status as part of the Master Plan, and a financial analysis of the earning ability of the field. This engineering analysis was separated into five divisions.

The financial analysis and estimated cost of putting Air Terminal No. 8 in condition[16] for airport operation, was as follows:

| *Division 1.—Physical Analysis of Site:* | | Percentage of total. |
|---|---|---|
| Total area of site, in acres | 968 | |
| Total acres that can be used for airport purposes if improvements in Division 2 are carried out | 935.73 | 96.67 |
| Acres subject to overflow of river and washes | 32.27 | 3.33 |
| Area (acres) unusable for airport purposes | 32.27 | 3.33 |

[15] Meteorological study was over the area as a whole.

[16] Does not include cost of land.

*Division 2.—Estimated Cost of Improving Site:*

| | | |
|---|---|---|
| Removing 877 acres of walnut trees, buildings, irrigation lines, etc | $40 000 | |
| Grading (west of flood control levee) 100 000 cu. yd. of cut and fill | 50 000 | |
| 29 000 lin. ft. of fence | 29 000 | |
| Drainage | 5 000 | $124 000 |

*Division 3.—Outstanding Bonded Indebtedness:*

| | | |
|---|---|---|
| El Monte School | $16 629 | |
| Mountain Avenue School | 342 | |
| Flood control | 5 351 | |
| County improvement | 19 722 | $42 044 |
| Total | | $166 044 |

*Division 4.—Estimated Cost of Equipment and Improvements for Airport Operation:*

| | | |
|---|---|---|
| Hangars with concrete aprons | $200 000 | |
| Lighting (flood lights, runway lights, boundary lights, beacon light) | 50 000 | |
| Administration building and depot | 40 000 | |
| Comfort stations | 3 000 | |
| Turfing 2 151 364 sq. yd. on runways and landing area | 129 082 | |
| Water supply development (pumps and storage) | 50 000 | |
| Telephone and telegraph system | 15 000 | |
| Meteorological equipment | 5 000 | |
| Sprinkling system for landing area and runways | 35 000 | |
| Road work | 10 000 | |
| Miscellaneous equipment (trucks, roller, blades, scarifier, tractor unit, ambulance and first aid equipment, fire equipment, and small tools) | 30 000 | $567 082 |
| Total | | $733 126 |

*Division 5.—Financial Analysis and Earning Ability.*—The study of finances and probable earning ability are arranged in Table 5.

*Summary of Financial Analysis.*—The foregoing items may be summarized as follows:

| | | |
|---|---|---|
| (A) Annual Earnings for 50-Year Period, 1930-1980: | | |
| Net annual profit on walnuts = $82.24 per acre (average) × 300 acres | $24 672 | |
| Average annual earnings over 50-year period. | | $275 460 |
| Average annual cost of operation and maintenance | $30 000 | |
| Annual interest on $733 126 (improvements) plus $2 500 000 (land) at 6% | 193 987 | 223 987 |
| Average annual net profit (50-year period) | | $51 473 |

(B) Ultimate Annual Earning Capacity of Site No. 8:

| | | |
|---|---|---|
| Anticipated ultimate population, San Gabriel Valley (Section 2-E) | 3 000 000 | |
| Anticipated airplanes in 1965, San Gabriel Valley | 6 000 | |
| Anticipated airplanes when San Gabriel Valley reaches 3 000 000 population | 30 000 | |
| 174 acres of hangar space at 3 cents per ft. per year | | $227 380 |
| Depot and administration office space rental, 50 000 ft. at $1.00 | | 50 000 |
| 100 acres available for shops, accessory houses, manufacturing plants, etc., at 10 cents per acre | | 435 600 |
| Expected annual revenue from concessions, landing rentals (student pilots), lockers, transport passenger tax and miscellaneous | | 50 000 |
| Ultimate annual earnings | | $762 980 |

As a result of this study, Air Terminal No. 8 was given the following rating:

| | |
|---|---|
| Surrounding topography | 10 |
| Physical condition of site | 20 |
| Location with respect to other fields | 10 |
| Accessibility | 13 |
| Transportation facilities | 10 |
| Utilities | 3 |
| Drainage | 5 |
| General desirability | 10 |
| Local hazards | 12 |
| Total | 93 |

TABLE 5.—Financial Analysis and Earning Ability, Air Terminal No. 8.

| | 1930 | 1940 | 1950 | 1960 | 1970 | 1980 |
|---|---|---|---|---|---|---|
| Population (San Gabriel Valley) | 250 000 | 480 000 | 625 000 | 750 000 | 900 000 | 1 050 000 |
| Number of airplanes (San Gabriel Valley) | 62 | 480 | 2 080 | 5 000 | 8 500 | 10 000 |
| Number of airplanes at terminal | 31 | 240 | 1 040 | 2 500 | 4 750 | 5 000 |
| Number of hangars required | 2 | 16 | 69 | 166 | 316 | 234 |
| Square feet of hangar space | 40 000 | 320 000 | 1 380 000 | 3 320 000 | 6 320 000 | 6 680 000 |
| Rental from hangar space | $ 1 200 | $ 9 600 | $ 82 800 | $139 200 | $259 200 | $400 800 |
| Revenue from manufacturing, accessories, etc | 2 000 | 8 000 | 20 000 | 40 000 | 80 000 | 160 000 |
| Revenue from taxi schools, landings, transports, etc | 300 | 2 400 | 20 700 | 25 000 | 27 000 | 25 000 |
| Revenue from utility service | 500 | 3 000 | 5 000 | 7 000 | 9 000 | 11 000 |
| Revenue from office service | 500 | 5 000 | 12 000 | 20 000 | 30 000 | 40 000 |
| Miscellaneous revenue | 100 | 500 | 2 000 | 5 000 | 8 000 | 10 000 |
| Total revenue | $ 4 600 | $28 500 | $142 500 | $236 200 | $413 200 | $647 800 |
| Net profit from walnut crop | $24 672 | $24 672 | $ 24 672 | ..... | ..... | ..... |
| Gross annual earnings | $29 272 | $42 172 | $167 172 | $236 200 | $413 200 | $647 800 |

Analyses and studies similar to the foregoing were made for each site. Then the best were selected, by the process of elimination, to serve the County

in a comprehensive way with airport facilities. The comprehensive plan was so designed and arranged that the existing airports which had received a satisfactory rating were properly recognized. The proposed airports were so arranged and situated as to serve the ultimate population and were so chosen that the development of the sites themselves could be accomplished if and when they were in demand. The official highway plan of the County was adjusted to conform to and preserve both the existing and the proposed airports.

The general procedure was to select, at a strategic location in each physical division of the County, a major air terminal, from which would operate transport planes, cargo planes, and all large aircraft.

*Definition of Major Air Terminal.*—A major air terminal is an airport of sufficient size to permit the safe and efficient operation of the largest transport planes that are now in service or likely to be placed in service. It must have a runway of at least 5 000 ft. in length and 400 ft. in width, or must be so equipped with apparatus or mechanism as to permit the taking off of planes in like number and with the same degree of safety as would the runway stipulated. It must also be able to provide a separate area that will permit landings in all directions. The dimensions of such landing area must be at least 2 500 by 2 500 ft., or must be equipped with apparatus or mechanism to accomplish the same effect in the matter of safety and number of landings as would the area stipulated.

A major air terminal must have sufficient area to enable the erection of storage hangars for at least 1 000 airplanes; it must have adequate space for shops, manufacturing plants, and a passenger and freight depot; and it must be adequately served by both rail and highway transportation facilities. It must also be so located as to serve, adequately, a large population, either actual or potential. Furthermore, it must be able to warrant the highest class airport rating of the Aviation Division of the Department of Commerce.

In each physical division of the Los Angeles County survey there were selected satellite fields to serve each community. Private ships, police planes, Army and Navy ships, taxi planes, and small craft will operate from these fields.

*Definition of Satellite Airport.*—A satellite airport is a field so designed as to accommodate ships smaller and of less wing spread than transport planes. It must be of sufficient size to permit the construction of a runway at least 1 800 ft. in length. It must also have hangar space for the storage of airplanes, such space to be commensurate with the population served.

The general purpose of a satellite field is to serve the owners of private planes, commercial taxi planes, light military planes, and police planes; also, to serve as emergency landing fields for larger planes in distress.

The satellite fields in Los Angeles County were so located as to be accessible by ground transportation not involving more than 10 min. of time from any point. In addition to serving the community with airport facilities for the present and future, in so far as private ships are concerned, these satellite airports give opportunity for aviation facilities for long-distance travel. This is accomplished by the operation of taxi planes from the satellite fields to the major air terminal, from which operate the large passenger ships.

The distribution of air mail to local points is accomplished in a similar manner.

Fig. 5 illustrates the comprehensive airport development plan for Los Angeles County. As each physical division of the County is surveyed and reported on by the Commission's technical staff and its Aeronautical Advisory Committee, detailed plans are prepared for the design and development of each recommended site.

FIG. 5.—PRELIMINARY COMPREHENSIVE AIRPORT DEVELOPMENT FOR THE COUNTY OF LOS ANGELES, CALIFORNIA.

*Step No. 6.—The Design of the Airport.*—Attention is given to the design of the major air terminal for the reason that the area involved and the design of the field itself must be commensurate with the population served. The future population density gives a fair basis for the facilities required. At the outset it is recognized that the major air terminals will have the greatest concentration of aircraft operation. The area of the immediate physical division that each major air terminal serves ranges from 200 to 300 sq. miles and an ultimate population of from 1 000 000 to 3 000 000.

One of the chief factors in the safety of the airplane as a means of transportation is the proper and efficient design of the airport. In the design of all major air terminals one of the basic principles that has been followed in the plan is to provide for the segregation of the landing area and the runways for taking off. Another is to have runways of sufficient length to permit landings on the field in the event of a "dead stick" or a "concked motor". It has been quite definitely established that these basic principles contribute to greater safety and efficiency. Such design will permit the simultaneous landing and taking off of a squadron of planes; it likewise permits the continuous landing or the continuous taking off of ships, on schedule or off schedule, with a large factor of safety and efficiency.

*Application of the Comprehensive Plan.*—It is generally recognized by those vitally interested in the future of aviation that it is essential that a systematic and comprehensive plan be followed. Those developing airports in Los Angeles County have the benefit of the impartial study and advice of the Regional Planning Commission and its Aeronautical Advisory Committee; and the selection of major air terminals or local fields, whether private or public, has closely followed the recommendations as set forth in the Master Plan.

The selection of a site in accord with the plan gives protection in the form of zoning; it provides for the proper construction and location of ground-transportation facilities, regulation of the height of structures in the vicinity of the field; and also guards against having the field declared a nuisance.

The financial set-up for the development of air terminals differs somewhat in each instance. If the purchase of any air terminal is to be made from public funds, it is the intention of the Regional Planning Commission of Los Angeles County that such purchase shall be made on the basis of its contribution as a part of the "Comprehensive Airport Development Plan".

*Summary.*—In stipulating the factors which have to do with the governing of airport locations, whether for large fields or small, it is essential that certain fundamental principles in city planning be recognized. Some of the important factors to be considered are those that have to do with the future growth and character of the community which the airport is to serve, always remembering that aviation is still in its infancy. The procedure being followed in Los Angeles County and the factors used have accomplished very satisfactory results.

When speed is considered, the element of safety plays a predominant part. The more speed that is acquired, the more safety is sacrificed. Travel by air will never be as safe as travel on the ground. Much can be done, however, to make air travel reasonably safe. The index of the safety factor now rests with the design, location, and adequacy of airport facilities. The majority of airplane accidents occur either when landing or taking off. If the same factor of safety can be incorporated in the design and location of airports as is accomplished in the design and construction of the plane itself and by the thoroughness of the pilots, aviation will indeed be a reasonably safe means of travel.

PERRY A. FELLOWS,[17] M. AM. SOC. C. E. (by letter).—This paper emphasizes some of the points that the writer has stated[18] on other occasions. The methods outlined have been used in a number of instances as an aid in selection of airport sites.[19]

There are two limitations that should be definitely borne in mind whenever an attempt is made to codify characteristics: First, such a method is a tool and should be used honestly for the reason that, just as with any other tool in the hands of those who so wish, it can be misused; and, second, the group best suited to make use of such a tool is the engineering group.

If these two principles are kept uppermost in mind the use of airport characteristics will avoid the criticism that otherwise may be met. There are people who oppose setting up such a classification as that recommended in the paper; especially do they oppose it on the grounds that it is possible for some one to believe that a way is thus made easy for the layman to select the best possible airport site. Such criticism can always be met with the cautionary advice that the instrument should be used only in its proper field and that its use should be entrusted only to the competent and qualified engineer.

W. W. CROSBY,[20] M. AM. SOC. C. E. (by letter).—To one who has been familiar with the development of County, State, and Federal Highway systems during the past thirty years or more, this paper has suggested some analogies of interest. Both airways, with their airports, and highways, with their foci or termini, are transportation systems. The locomotion may seem quite different, but certain principles are common, and airships do "land" even though, as the author suggests, air and water navigation have much in common.

When the highway systems were first started, every little village fought strenuously to have the improved roads run through it and along its main street. As the expansion of the systems took place, and such transcontinental routes as the "Lincoln Highway" were conceived, officials in the larger cities also fought for the routes to run through their territory.

A few years ago a reaction took place. The same places began to appeal piteously to the highway authorities for the removal of the through traffic to by-passing routes so that the localities might be relieved from the serious dangers and damages caused to the local use of the streets by the through traffic; and a general movement along this line is already under way.

It seems to the writer that analogies accompany these facts; and he believes that they should be seriously considered in connection with the problems of airport location.

In this same connection a detail of airport construction may have some weight. May not the developments in airport surfacing have some effect on location just as the developments in highway surfaces have affected highway location?

[17] City Engr., Detroit, Mich.

[18] *American City Magazine*, May, 1928, and a more complete discussion in the Associated Technical Societies *Bulletin*, April, 1928, reprinted in *Engineering News-Record*, September, 1928.

[19] "Standards and Score Card for Municipal Airports," by N. L. Engelhardt, Jr., *Airway Age*, October, November, and December, 1928.

[20] Cons. Engr., Coronado, Calif.

Formerly, many conflicting factors influenced the type of surface necessary on highways. For example, smooth, hard surfaces were not suitable for slow, horse-drawn traffic and vehicles with metal tires that ground the road surfaces into dust. As the motor traffic has become predominant on many systems of highways it has simplified the problems of surfacing by removing these conflicting factors, so that the traffic is composed only of soft-tired vehicles which require smoothness and which create no detritus. Curves are required to be flatter, visibilities must be longer, and grades may be steeper; but alignment should be more direct and widths must be greater. To give general satisfaction surfaces may be less varied and more "standard".

May not some of the developments in air vehicles, that now seem quite probable to threaten, similarly affect the decisions as to airport construction and location? For instance, suppose that a mechanical modification in the wing of a plane should be developed so that a plane could check its horizontal speed and drop gently, and almost vertically, to its landing. Would not the allowance for "gliding angle" in airport location be reduced? Similarly, if the airplane could be checked in its forward movement, would not the necessity of depending on the friction of the tires or the tail-skid for this result be relieved so that the surfacing of the landing field could be simplified and improved? Possibly, also, the rising angle of a starting plane could again be increased, and the location again affected. These results might affect the size of the area required and thus enable locations to be made advantageously where now they seem impossible.

Furthermore, if an airport may be regarded as something distinct from an airfield, may not the location problems of the former be simplified? Why should not the housing, repairing, fueling, oiling, tuning-up, and such work go on in convenient but separated "yards" or "docks" (as in the case of railroads and shipping lines), so that the ports or depots might be located with the convenience to the passengers that is necessary for commercial popularity? Certainly training or practice activities are not necessary functions of airports.

Even in the new art of airway engineering, it seems to the writer, after considering the many mistakes that have been proved on him as well as on others in years of highway engineering, the saying that "the wise man learns from the experience of others; any one can learn from his own", is still worth remembering.

E. K. SMITH,[21] Assoc. M. Am. Soc. C. E. (by letter).—The considerable increase in air passenger traffic, quite largely due to the lowered passenger rates, and the increase expected in express service should cause special importance to be placed on certain of the factors in airport location covered in Mr. Baker's paper. These are, particularly, the physical features, the accessibility to the community served, and the ground transport facilities to and from the airport. For mail service alone facilities for transport to and from the airport will not be so important. It is probable that within a few years all major airports will have pneumatic tube service from the main post office.

[21] Asst. Mgr., Highways and Municipal Bureau, Portland Cement Assoc., Chicago, Ill.

For a purely express or mail business the surroundings, appearance of the field, etc., do not play as important a part as they do for passenger traffic. Air transportation offers to-day a specialized service for passenger transportation already realized and seeing each year fast improvement in air equipment. Nevertheless, as stated by C. M. Keys, President of the Transcontinental Air Transport Company:[22]

"Only 10% of aviation is in the air; 90% of it is on the ground.

"As regards passenger carrying on a transcontinental scale, that is probably an under-statement; the ratio between ground preparation and actual flight is likely to be wider than that."

For all three classes of performance (mail, express, and passenger), air transportation offers a highly specialized service, superior in speed to any other form. While it is yet seriously handicapped by unfavorable weather conditions, the most unfavorable weather also handicaps highway and railroad service, sometimes for a much longer time.

To build up the general public use of air service, it is already evident that greater attention must be paid to permanence and stability of construction on carefully designed airports, with special attention to the appearance of the airport and the provision of comfort for passengers. The public is already educated to expect and secure comforts and conveniences at railroad stations and bus terminals that were unheard of a few years ago. Without reasonable provision for corresponding conveniences at airports proper development of air transportation cannot be expected to continue steadily at the desired rate. Even in the appearance of the field, the buildings should not be mere sheds or brick barns, but should give, without undue expense, the appearance of careful design and stability suitable for an established industry giving important daily service to the public. Hotels, restaurants, rest rooms, etc., are already making their appearance at American airports as they have for several years past in Europe. Certainly it is reasonable to expect a just proportion of this cost as a proper operating cost of the field to be returned from the field charges for service.

Therefore, in locating the airport, consideration must be given to the ease with which the physical features may be adapted to providing facilities for the comfort and convenience of air passengers. It is also evident that for a number of years to come, the fields will be visited by thousands of people to see shows, races, etc., or merely to observe the daily business of the field. This has already been capitalized at European airports where amusement and athletic parks frequently adjoin the field and where grand stands are frequently supplied for the use of spectators. A voluntary attendance of many thousand people at any municipal air field is an advertising asset far more important than that which can be secured by thousands of dollars worth of paid newspaper and magazine publicity. The impression carried away by these people and passed on by them to their friends will be of the highest importance.

A location for the airport that makes it easily accessible to visitors, a site large enough to provide ample parking space in addition to the bare necessities for planes, and, if practicable, a location and surroundings that present an

[22] *Chicago Herald and Examiner*, Interview, November 4, 1928.

attractive appearance, are features of real value to the community. Provision of rest rooms and observation stands will encourage the public support of the airport. These are facilities freely provided in any park or other place of public gathering. The airport, to-day, is in many respects more important than the public park, or it should be made so. Paved sidewalks and paved drives and aprons around the hangars are equally important as effecting the comfort of visitors and patrons and keeping them free from mud and dirt.

It has been suggested that present condition of the ground surface will affect the choice of an airport location. This is especially true in so far as it affects the drainage required, etc. It is certain that paved runways for landing and take-off will shortly be a necessity at most of the important airports. A turf or light surface satisfactory a few years ago for the use of light planes will no longer serve the hundreds of heavy transport planes coming into use.

A tabulation has been published[23] which shows twenty-seven standard models of airplanes weighing more than 5 000 lb. A considerable number in transport service to-day weigh more than 10 000 lb. and the Boeing Air Transport Company and the Western Air Express are placing planes in long-distance transport service weighing, respectively, 17 500 and 22 000 lb.

The U. S. Department of Commerce, as a result of tests, states that the landing load should be increased 100% to allow for impact. This brings a wheel load on the surface of the field ranging from 5 000 to 22 500 lb.

Another factor requiring paved runways for safety and economy is the reduced distance required for take-off. On its flight to America, with complete load of fuel, the *Bremen* required a starting run of only 1 800 ft. on the Portland cement concrete runways at Dessau, Germany. At Baldonell, in Ireland, where the Atlantic flight was actually started, 4 750 ft. were required for take-off from the runways of rolled cinders and ashes in spite of the smaller load on the ship.

Despite the shortage of money for building purposes in Germany, concrete runways have been constructed during the three years since 1927 at Dessau, at the Halle-Leipzig Airport, at the Travemünde Airport, Frankfurt-am-Main, and at the Giessen Airport. In this country, concrete runways similar to the highest type of highways have been constructed at the New York City and Detroit Municipal Fields, at the Curtiss-Steinberg Field, at East St. Louis, Ill., and a number of others. It is evident that the character of the present field surface no longer plays as important a part as formerly in determining airport location since for any important airport a paved surface will be provided to support the heaviest planes, reduce the length of take-off, and greatly reduce the maintenance required on the remainder of the field.

CLYDE M. WOOD,[24] M. AM. SOC. C. E. (by letter).—The factor of an adequate water supply for fire fighting needs more consideration than has been given in the location of most airports. Given two or more locations where the other factors are evenly balanced, the site offering an established, adequate water supply should be selected. The water supply at available sites

[23] *Aviation*, January 18, 1930.

[24] Engr., Executive Div., "Automatic" Sprinkler Corporation of America, Cleveland, Ohio.

is generally woefully inadequate or non-existent, but when the reverse is true, advantage should be taken of the fact.

When an industrial plant is built with the same degree of isolation, the same number of square feet of floor area, and the same value of building and contents per square foot as is found at the average airport, great care is taken to provide an adequate water supply for protection against fire; and the fire hazard is infinitely more severe in a hangar than in the average industrial building.

The severity of this hazard requires large quantities of water instantly applied not only through the overhead open sprinklers on top of the planes, but also through open floor sprinklers on the under surfaces of wings and fuselage. Therefore, relatively larger supplies are required for hangars. The usual 6-in. or 8-in. main with fair pressure which is sufficient for the average industrial plant is not enough, especially for the larger hangars. For fire protection purposes the water main may be required to supply as much as 3 000 to 4 000 gal. per min., in a hangar, 120 by 120 ft.; and more in larger hangars.

The Detroit City Airport was fortunate in being placed alongside a 36-in. city main with a dependable pressure. On account of the unusual size of this hangar, a 24-in. main was connected to the 36-in. city main, and extended into the hangar. An 8-in. main, because of its close connection to 12-in. and 16-in. mains, was sufficient for the Colonial Hangar at the Newark, N. J., Metropolitan Airport. It is readily seen that because of the friction losses induced by these unusual discharges larger supply pipes are required than are needed for ordinary buildings.

The fact that a gravity tank must be located at a distance from the landing field equal to seven times its height is another reason for selecting a site near an established water supply. Space outside the airport for a tank can be purchased; also right of way for an underground main from tank to hangar, but these considerations are too often overlooked until after the airport site has been selected.

In lieu of a gravity tank as a fire protection supply, large automatic pumps may be used. Here, again, arises the problem of space for the huge reservoir necessary to supply the pumps, for the usual 100 000 gal. is not enough. Somewhere, some day, some engineer is going to provide or utilize a basin beside a land airport for seaplanes, and use the basin water as a reservoir for fire pumps.

That automatic sprinkler protection against fire is one of the major considerations in selecting airport sites is amply attested by the fire record in airplane hangars. The National Fire Protection Association reports a list of fifty-one fires between January, 1928, and July, 1930. The extent of the loss is given for forty-four of these fires as $2 540 700, or an average of $57 743 per fire. Thirty-nine of them destroyed 223 airplanes besides many hangars and much equipment. This is rather "bad medicine" for an infant industry, and a challenge to airport engineers. No other industry is tolerating such fire losses.

DONALD M. BAKER, M. AM. SOC. C. E. (by letter).—The effort was made in the preparation of this paper to emphasize the relationship of an airport to the entire city or regional plan, and also to set up certain fundamental requirements as a guide for the use of those who are responsible for the selection of sites for airports. The system of rating was suggested primarily as a mechanical device whereby various sites which might be offered for consideration could be compared, one with another. Whenever this method is used as a basis of comparison, the actual items specified are not so important (provided some judgment is used in selecting them), as the method whereby they are applied and the fact that they must be applied uniformly to all subjects being judged. Without question, each of the ten points suggested by the writer could have been subdivided into from two or three to a dozen sub-headings, each of which in itself could have been given a proper weight. This system was used by the writer early in 1928.

The paper referred to by Mr. Fellows[25] illustrates the detail to which such systems of rating may be carried. It was not felt necessary to go into such detail in the writer's paper, as it was thought that any one using the method could, with better results, expand the ten points given. The weights suggested for each factor were suggestive only and might be varied, depending on the different uses to which the field to be selected was put, the main point being that all sites should be compared by the same measuring stick.

The writer does not agree with Mr. Nolen's suggestion as to the elimination of the factor of legislative control. Unless all sites under consideration are within the limits of an incorporated city where zoning and police regulation exist, it is very essential that some measure of control be placed over the development surrounding the airport, in order that height of buildings, use of property, development of highways, etc., may be regulated. If the site lies within unincorporated territory, proper co-operation on the part of county officials may affect this, but if this co-operation cannot be obtained it constitutes a serious drawback.

Accessibility, which should be expressed in terms of time, and not in terms of distance, is primarily an economic factor that can be evaluated in most cases in terms of dollars and cents. In a large metropolitan center, secondary airports will become absolutely essential for private planes used primarily in short hops. These secondary sites, however, can be made relatively small in size, but should be located, of course, so as to be accessible to the better class residential sections of the city wherein will reside most of those using this type of air transportation. The writer is still convinced, however, that the ultimate commercial load in air travel will be the long haul, in which case accessibility to the heart of the city, if maintained within reasonable limits, is not so important. Shore-haul passenger traffic has, of course, been developed to a considerable degree, but until night flying comes into existence as a regular feature, passenger travel between cities 400 to 600 miles apart, will not show much saving of time during business hours. At present, traveling can be done in such cases by rail by leaving the office after closing hours, arriving

[25] See footnote, p. 308.

at one's destination the next morning, having a full business day, and returning the following night, whereas travel by air made during daylight hours does not show any comparable saving of business hours. The gradual reduction in fares for aerial transportation, however, is increasing its popularity. The distance which a major traffic air terminal is located from the heart of the city in the final analysis becomes a question of adjusting capitalized cost of added distance from the business center against the cost of land necessary for the site, and arriving at a minimum total cost. Land cost varies inversely with the distance from the center of the community, and 5 min. in time distance may mean a vast sum in land investment.

Rapid transit lines are likely to serve the transportation needs of an airport better than highways, although any site should be located so that large crowds may have ready access to it on important occasions. The question of space necessary for landing and take-off areas is one that is still open to discussion. In 1928 much discussion was extant as to the probability of reduced landing and take-off speeds and consequent size of landing and take-off areas, but nothing has appeared during the intervening two years which would indicate that any smaller areas can be used satisfactorily. Ships are getting larger, and more of them are coming into use, resulting in greater crowding of airports. This point also must be kept in mind—that if in the future excess land has been acquired for an airport site, it can always be disposed of at a profit or used to good advantage for park or recreational purposes. The basis of rating given was primarily to apply to the sites to be used and not to the finished field.

The writer agrees with Mr. Angell in his statement as to the desirability of having surface fields, and also with Mr. Marsh as to the need for recreational facilities. This is one situation which can be far better cared for at publicly owned than at privately owned airports. In the latter every possible acre of ground must be made to pay revenue, and a private owner cannot afford to devote a large space to recreational facilities or allow excessively large areas for automobile parking.

The writer heartily agrees with Mr. Nolen's statement that an airport is essentially an industrial establishment, not only through the attendant activities and development which will surround it, but by virtue of the noise, crowds, dust, etc., which must exist even at the best regulated port.

Mr. Grimm's discussion and the re-arrangement of governing factors brings out a point the writer had in mind. The factors must be given different weights when applied to fields used for different purposes. Accessibility and transportation are far more important in a small field used by owners of private planes for business or pleasure purposes than in the case of a major terminal, and, at the former, meteorology is not so important since departures and landings are not usually made on schedule. The factors given by Mr. St. John illustrate the same thing, although the writer believes that probably too much weight is given by him to meteorology, which totals 30 points in Factors 1, 2, and 6. It is not thought that Item No. 13 in Table 1 is necessary. The airplane factory sites should come to the airport and the

port should not go to the factory. His Item No. 7, "Prospective Neighborhood Development", would be one sub-factor under the writer's factor, "Legislative Control."

The writer is very familiar with the excellent work being done by the Los Angeles County Regional Planning Commission in the development of a regional plan of airports in that county, which is referred to by Mr. Fox. The latter's discussion brings out very admirably the method and study which was suggested by the writer as a preliminary to the selection of any site or sites, and emphasizes the necessity of a comprehensive airport plan for any region.

Aeronautical transportation is here to stay, and the sooner the fact is accepted by the general public, including officials, the sooner they will realize that a regional plan of airports is just as essential as a regional plan of highways, and the more money will be saved in the ultimate acquisition of such sites. Mr. Fox's illustration of earning ability of Air Terminal No. 8, in the San Gabriel Valley, California, is very apt. It shows the proper economic approach to the matter and develops the fact that in the future airports can undoubtedly be classed as publicly owned utilities of a self-supporting nature.

The writer is much gratified with the general discussion which the paper has brought out, and hopes that the importance of airports in the general city or regional plan has been emphasized. Private companies, as well as public agencies, should realize that the location of an airport is a major factor making for its success, both from the standpoint of the port itself and of its service to the community. Much has been learned by railroads through experience in improper location of terminals and subsequent re-arrangements. No site should be chosen by any community until its location has been given the most thorough study.

# SPILLWAY DISCHARGE CAPACITY OF WILSON DAM[1]

By Louis G. Puls,[1a] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Cecil E. Pearce, J. H. Jones, and Louis G. Puls

## Synopsis

This paper describes the current-meter discharge measurements made on the spillways at Wilson Dam. The readings were taken for several gate-openings from 3 ft. to full gate and under two conditions, namely, no discharge and full discharge through the adjacent spillways. The head on the crest was 18 ft. Discharge quantities, together with the calculated coefficients for the several partly opened gates and also for full gate, have been obtained.

## Introduction

In view of the fact that nearly every dam built recently has an overflow spillway, the discharge of which is controlled by regulating gates of various types, there is a great need for information as to the discharge capacity of these openings. Although experiments have been made and results published on sharp-edged weirs discharging under low heads, very little has been done to supply data as to discharge capacities of spillways with round crests and variable gate-openings under the higher heads, for example, those up to 18.0 ft. It is not a surprising circumstance that such investigations have not been made. Entirely aside from the expense involved, it is not an easy matter to control conditions in order to obtain this information accurately, because a jet of water, 15 ft. in depth, traveling at the rate of 27 ft. per sec., is a rather treacherous mass of energy.

Nevertheless, this work was attempted, inspired by its need and value to hydraulic science, and results have been obtained which are here presented as a pioneering effort.

## Description of Spillway

The spillway section consists of a gravity overflow dam with the crest about 80 ft. above the bed of the river. On the crest there are provided fifty-eight

[1] Published in October, 1929, *Proceedings*.

[1a] Care, Hugh L. Cooper & Co., Inc., Kitchkas, Ukraine, Union of Socialistic Soviet Republics.

spillway openings formed by the spacing of concrete piers which serve the double purpose of supporting the regulating gates and the arches of a highway bridge. The clear openings are each 38 ft., and the piers are 8 ft. thick. The gates are 39 ft. 3 in. long by 18 ft. high.

The profile of the top of the overflow section, up stream from the seal, has the shape of an ellipse, with the equation, $\frac{x^2}{36} + \frac{y^2}{9} = 1$, the major axis being horizontal and 3 ft. below the crest. (See Fig. 1 (*a*).) The horizontal distance from the up-stream face of the dam to the gate seal is 6 ft. Down stream from the seal the curve is a parabola, with the equation, $42.585\ x = y^2$, the axis of which is vertical and coincides with the minor axis of the ellipse, the origin being at the crest. The up-stream side of the piers is semi-circular in horizontal section, with a radius of 4 ft., that forms a half round nose against the flow of water.

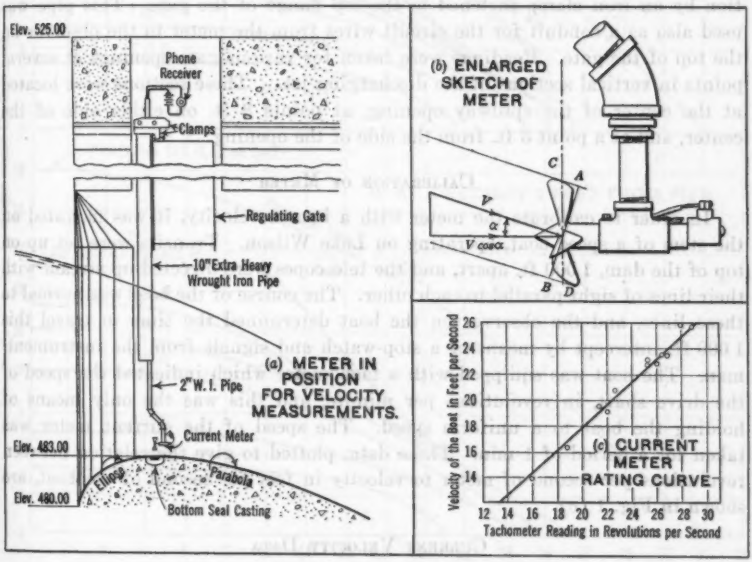

FIG. 1.—ARRANGEMENT OF MEASURING DEVICES.

## METHOD OF MEASUREMENT

The Price meters available were designed primarily for comparatively low velocities, up to 4 or 5 ft. per sec. Therefore, it was necessary to construct a meter with bearings capable of withstanding the high velocities of the spillway flow, which are as much as 27 ft. per sec. This meter was designed and built by the writer in the job machine shops. The propeller has three blades, is 4 in. in diameter, and is mounted on a small shaft which has thrust-bearing against the supporting casting. A worm was machined on the end of the shaft, so that it meshed with a wheel, into the face of which was set a small pin.

This pin, in revolving, came in contact with a fine wire terminal and thereby closed a dry-cell battery circuit and caused a clicking sound in the headphone. The ratio of the speed of the propeller to the worm wheel was 20 to 1.

This meter was mounted on the end of a 2-in. wrought-iron pipe in such a manner that the plane of the propeller coincided with the plane of the up-stream side of the gate (see Fig. 1 (*a*)). For all readings at points deeper than 4 ft. in flowing water, a 10-in., extra heavy, wrought-iron pipe supported the 2-in. pipe. In order to place the propeller in the plane over the seal, it was necessary to offset the meter a few inches down stream, and this was done by 1-in. pipe-and-ell fittings connected to the end of the 2-in. pipe (See Fig. 1 (*b*).)

The 2-in. pipe support was sufficiently strong to allow the meter to penetrate 4½ ft. of flowing water. This support was about 32 ft. long and, when placed vertically against the up-stream side of the gate, was held in that position by an iron clamp fastened to the top flange of the gate. This pipe was used also as a conduit for the circuit wires from the meter to the observer on the top of the gate. Readings were taken for various gate-openings at several points in vertical sections of the discharging jet. These sections were located at the center of the spillway opening, at points 8 ft. on either side of the center, and at a point 3 ft. from the side of the opening.

### Calibration of Meter

In order to calibrate the meter with a known velocity, it was mounted on the stem of a speed-boat, operating on Lake Wilson. Transits were set up on top of the dam, 1 000 ft. apart, and the telescopes were directed up stream with their lines of sight parallel to each other. The course of the boat was normal to these lines, and the observer on the boat determined the time to travel this 1 000-ft. intercept by means of a stop-watch and signals from the instrument-man. The boat was equipped with a tachometer which indicated the speed of the drive shaft, in revolutions per minute, and this was the only means of holding the boat to a uniform speed. The speed of the current meter was taken for a period of 1 min. These data, plotted to give the relation between revolutions per second of meter to velocity in feet per second of the boat, are shown in Fig. 1 (*c*).

### Current Velocity Data

As is customary, the metered results obtained in the field were arranged in tabular form. The gate-opening for each reading was given; and the elevation of pool level, the exact position of the meter in the discharging area, and the speed of the propeller were likewise given. From the calibration curve (Fig. 1 (*c*)), the velocity of the water was computed and, finally, this velocity was corrected to give results under a uniform head of 18.0 ft. which placed the pool level at Elevation 501.0 (normal operating pool level).

In these measurements it has been assumed that the velocity as recorded by the meter is the horizontal component of any diagonal flows which may exist. The shaft of the meter was supported as rigidly as possible in a horizontal position. Thus, in Fig. 1 (*b*), it is most reasonable to assume that the velocity,

$V \cos \alpha$, multiplied by the area in the plane, $C\,D$, is equal to the velocity, $V$, multiplied by the area in the plane, $A\,B$. The area in the plane, $C\,D$, is in the vertical plane over the crest.

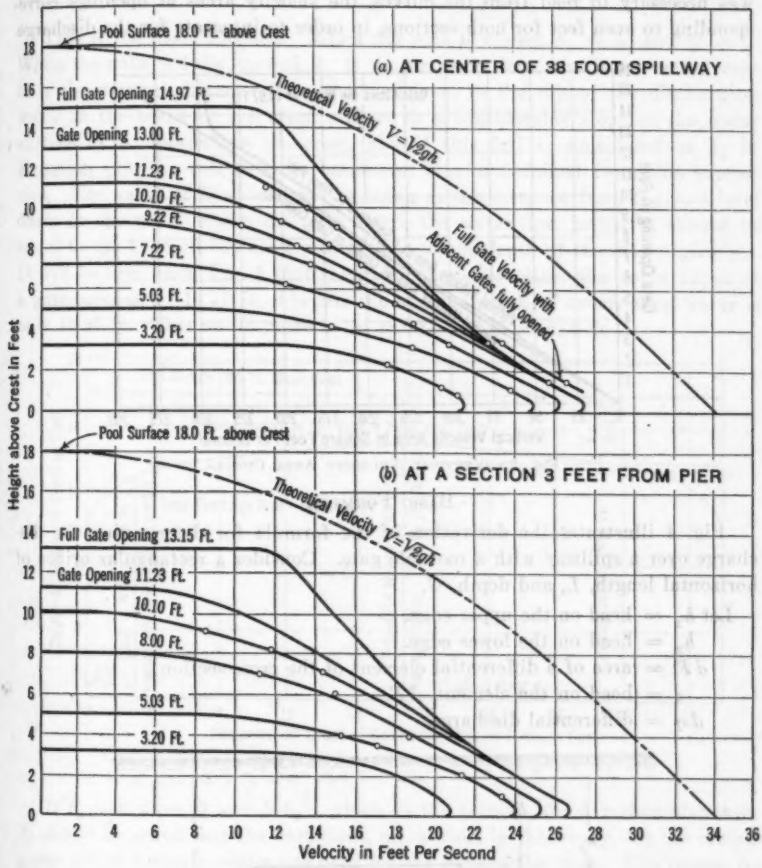

FIG. 2.—VERTICAL VELOCITY CURVES.

From the data thus collected curves were drawn showing the relation between gate-opening and the intensity of velocity for various depths below the bottom of the gate. Fig. 2 (*a*) shows the vertical velocity curves for a section at the center of the gate, and Fig. 2 (*b*), those for a section 3 ft. from one end of the spillway.

The areas under the curves of Fig. 2 (*a*) and Fig. 2 (*b*) were measured with a planimeter, and the results obtained were plotted so as to give a curved-line relation between the gate-opening, in feet, and the vertical velocity area, in square feet per second, for the two sections of the discharging jet; that

is, in Fig. 3, the values plotted for the vertical velocity areas are the products of water depth and average velocity for the various gate-openings shown in Fig. 2 (*a*) and Fig. 2 (*b*). Since these points were at odd gate-openings, it was necessary to read from the curves, the velocity areas at openings corresponding to even feet for both sections, in order to integrate for the discharge.

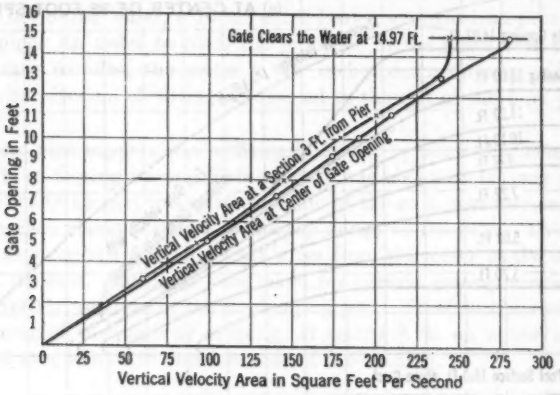

FIG. 3.—VERTICAL VELOCITY AREA CURVES.

## BASIC FORMULA

Fig. 4 illustrates the derivation of the formula for determining the discharge over a spillway with a movable gate. Consider a rectangular orifice of horizontal length, $L$, and depth, $G$.

Let $h_1$ = head on the upper edge.
$h_2$ = head on the lower edge.
$dF$ = area of a differential element of the cross-section.
$z$ = head on the element, $dF$.
$dq$ = differential discharge.

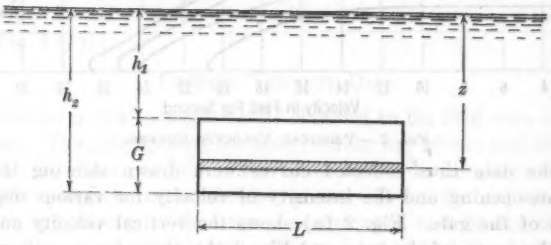

FIG. 4.

Then, $dq = \sqrt{2g}\, z\, dF$, and the discharge for the entire orifice is the integral of this expression for the entire area, $F$. Therefore,

$$Q = \sqrt{2g}\, L \int_{h_1}^{h_2} z^{\frac{1}{2}}\, dz = \frac{2}{3}\sqrt{2g}\, L \left( h_2^{\frac{3}{2}} - h_1^{\frac{3}{2}} \right)$$

For the actual case, the rate of discharge is found by applying a coefficient to this ideal value. The result may be written,

$$Q = m\,L\left(h_2^{\frac{3}{2}} - h_1^{\frac{3}{2}}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

This is the basic formula. When the gate is closed, $h_1 = h_2$ and $Q = 0$. When the gate is fully opened, $h_1$ is theoretically zero, but in an actual case it is the vertical distance from the pool level to the top of the discharging water in the plane of the crest. There is a considerable slope to the water surface as it approaches the crest, and if this fall is considered as $h_1$ in Equation (1), the full gate discharge can also be obtained from this expression. The value of $h_1$ should not be taken as the distance from the pool level down to the point where the gate clears the water, but rather it should be equal to the head on the crest minus the average depth of the discharging jet. It will be seen from Fig. 5 that the gate completely clears the upper nappe at a gate-opening of 14.97 ft., whereas the average depth of overflowing water is only 13.95 ft. This would make $h_1 = 18.00 - 13.95 = 4.05$ ft.

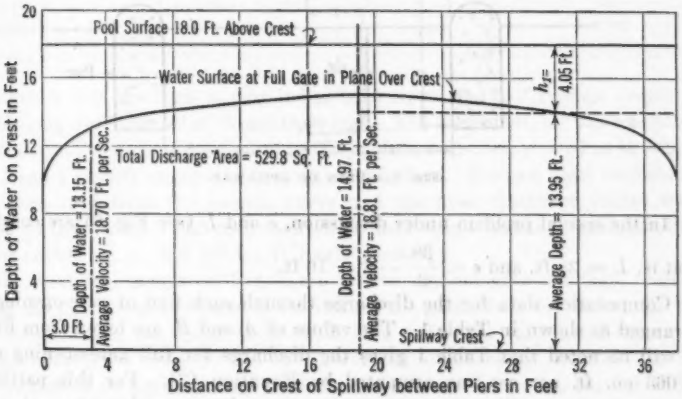

FIG. 5.—WATER SURFACE AT THE CREST WITH FULL GATE-OPENING.

If $h_1 = 0$, then $Q = c\,L\,h_2^{\frac{3}{2}}$, which is the formula for a rectangular weir. It should be noted that the coefficient, $m$, is used, in this study, for the rectangular orifice formula, while $c$ is used for the rectangular weir. The reason for this is that the coefficient for the latter is different, due to the fact that $h_1$ is assumed equal to zero.

## DISCHARGE FORMULA WITH GATE PARTLY OPENED

To determine discharge it is necessary to express the vertical velocity area as a function of the length of the spillway and to integrate between the limits of this length. Since it varies increasingly from the pier to the center of the gate-opening, according to some function (most probably of the second degree), the vertical velocity area can be expressed as a function of this distance by the equation of the parabola. No doubt there is a rapid decrease

in the rate of change in this area within a few inches from the masonry pier and, consequently, the curve departs from any definite function of the spillway length. However, the percentage of error is small and can be neglected. The equation of the parabola:

$$x^2 = 4p\ (y - A) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

is established by solving for the constant, $p$, in terms of $A$, $B$, and $e$ (see Fig. 6). The vertical velocity area, as found from Fig. 3, is here designated as the ordinate, $A$, and in moving according to Equation (2), between the limits of $x = 0$ and $x = \frac{L}{2}$, it will generate a volume representing one-half the discharge. The derived equation for the total discharge of one spillway will be,

$$Q - A\ L = \frac{(A - B)\ L^3}{12\ e^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

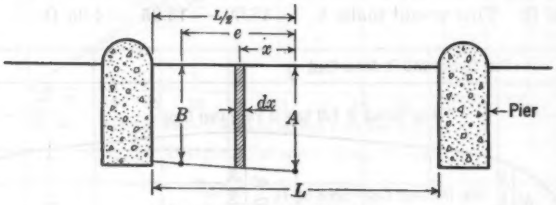

FIG. 6.—PLAN OF SPILLWAY.

In the special problem under discussion, $e$ and $L$ (see Fig. 6) are constant; that is, $L = 38$ ft. and $e = \frac{38}{2} - 3 = 16$ ft.

Computation data for the discharge through each foot of gate-opening are arranged as shown in Table 1. The values of $A$ and $B$, are taken from Fig. 3. It will be noted that Table 1 gives the discharge for full gate-opening to be 10 063 cu. ft. per sec., as computed by Equation (3). For this particular opening, the parabolic curve integration may give a result greater than the actual, due to the greater difference in the velocity areas, $A$ and $B$. If the velocity area at $A$ is divided by the depth of the water at that point (see Fig. 5), the average velocity for the section is $\frac{281.6}{14.97} = 18.8$ ft. per sec. Similarly, the average velocity for the section, $B$, is $\frac{245.9}{13.15} = 18.7$ ft. per sec. This shows the average velocity to be nearly equal in the two sections. The total area of the discharging jet at full gate is 529.8 sq. ft. (see Fig. 5). This will give a discharge of $529.8 \times 18.75 = 9\,925$ cu. ft. per sec.

The surface of the water is not level from pier to pier in the plane of the crest at full gate-opening. The round-nosed piers do not fully suppress the contraction at the surface, the water being compelled to make further contraction because of the diagonal flows. This crowding tendency toward the center forms the elliptical curve as shown in Fig. 5. It is noted that the gate

would clear the water at the 14.97-ft. opening, while the average depth is 13.95 ft. In computing values for the coefficient, $m$, in Fig. 7, this average depth was subtracted from the total head of 18.0 ft. on the crest to obtain the value of

TABLE 1.—COMPUTED DISCHARGE WITH ADJACENT GATES CLOSED.

$h_1$, which is 4.05 ft. This is why it has been correlated to "Average Depth of Discharging Jet" instead of "Gate-Opening". The coefficient, $m$, was computed for these conditions by Equation (1). The points were then plotted as shown in Fig. 7 and a smooth curve was drawn through them. Revised ideal coefficients were then read from the smooth curve and the final discharge values were computed from them. The coefficient, $c$, in the Francis formula, corresponding to this coefficient, $m$, is 3.420 for full-gate discharge.

The discharge curves on Fig. 7 are plotted against gate-openings, thereby giving the maximum discharge at the instant the gate clears the water. As the gate rises through the upper 12 in. of flowing water, the tangent of the curve rapidly approaches infinity, and the increment of discharge becomes less for any increment of gate-opening until the gate clears the water, beyond which instant, obviously, the increment of discharge is zero.

### DISCHARGE CAPACITY OF SPILLWAY WITH ADJACENT GATES OPEN

The discharge of one spillway is increased materially if the adjacent openings are discharging at the same time. This increase in quantity discharged can be treated as if it were due to an increment of head. Thus, if the head, $H$, produces a discharge, $Q$, with adjacent gates closed, $H + \Delta h$ will produce $Q + \Delta q$ with them opened, wherein $Q$ can have, without appreciable error, the same ratio to $Q + \Delta q$ as the ratio of the three halves power of the heads, or,

$$\frac{Q}{Q + \Delta q} = \left(\frac{H}{H + \Delta h}\right)^{\frac{3}{2}}$$

Since the values of $H$ and $Q$ are known (see Table 1), it remains to find $H + \Delta h$ before it is possible to solve for $Q + \Delta q$. In order to determine the

head, $H + \Delta h$, it is only necessary to meter the velocity at a short distance above the crest, and then solve for the increment of head necessary to increase the velocity curve, under the condition with adjacent gates closed, to coincide with the metered points under the condition with the adjacent gates opened.

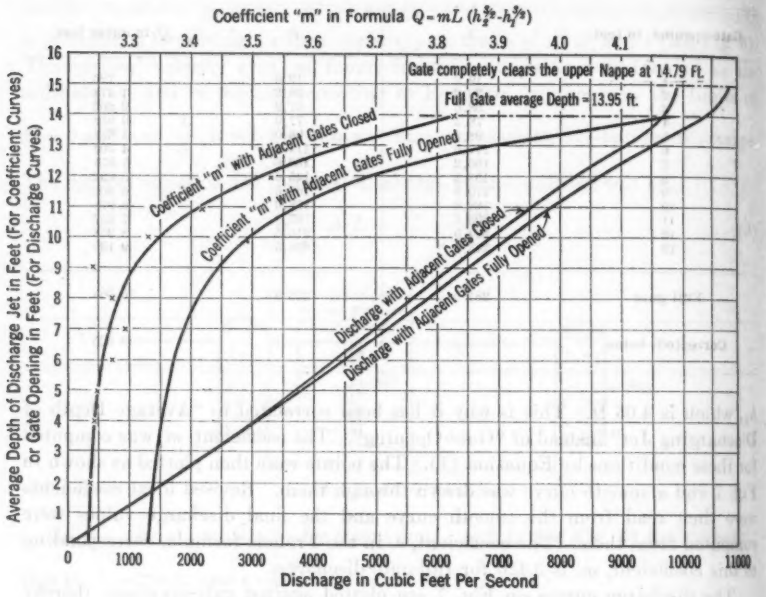

FIG. 7.—COEFFICIENT AND DISCHARGE CURVES.

At the center of the spillway, with full gate-opening, at an elevation of 2.0 ft., above the crest, the velocity is 24.8 ft. per sec. under the first condition and 25.6 ft. per sec. under the second condition (see Fig. 2 (*a*)). Since the head of 16.0 ft. produced the velocity of 24.8 ft. per sec., a head of $16\left(\frac{25.6}{24.8}\right)^2 = 17.08$ ft. may be expected to produce the velocity of 25.6 ft. per sec. This is equivalent to raising the pool level to $17.08 + 2.0 = 19.08$ ft. above the crest instead of 18.0 ft. as in the first condition. It follows that the effect on the discharge of the intermediate spillway of opening the neighboring gates fully, is similar to that of raising the pool 1.08 ft.

By using the formula,

$$Q' = Q\,\frac{h_4^{\frac{3}{2}} - h_3^{\frac{3}{2}}}{h_2^{\frac{3}{2}} - h_1^{\frac{3}{2}}} \qquad \ldots\ldots(4)$$

in which, $Q'$ equals $Q + \Delta q$, and $h_4$ equals $H + \Delta h$, the discharge, $Q'$, can be found because all other values are now known. Equation (4) holds good not only for full gate-opening, but also for gates partly opened, in which the

values of $h_3$ and $h_1$, the respective heads on the top of the jet, must be introduced.

The curves of Equation (4) are plotted in Fig. 7 for the two conditions: Adjacent gates closed and adjacent gates fully opened. By picking the proper discharge values from these curves, the corresponding values of $m$ may be determined by making the necessary substitutions in Equation (1). The corresponding, deduced coefficient, $c$, in the Francis formula for full gate discharge, is 3.738.

### Discharge of One Opening Under Condition of Adjacent Gates Partly Opened

Fig. 7 shows the discharge of one opening under the conditions that both adjacent gates are either closed or fully opened. Although no measurements were made when one adjacent gate was open and the other closed, it is reasonable to assume that, under this condition, the discharge would be the mean of those determined from the two curves. Thus, if one adjacent gate were closed and the other fully open, the discharge of the intermediate 8.0-ft. opening would be $\frac{5\,583 + 5\,801}{2} = 5\,692$ cu. ft. per sec.

If the adjacent gates were open a small distance compared to the intermediate gate, the effect on the discharge of the latter, no doubt, would be negligible.

If each of the adjacent gates was opened as much as the intermediate gate, the effect would be slightly less than under the condition of adjacent gates fully opened, because every particle of water in the neighboring regions for the depth of the opening is in motion and, therefore, the retarding influence is removed.

### Total Spillway Capacity of Wilson Dam

With adjacent gates fully opened, the discharge of one 38-ft. spillway under a head of 18 ft. on the crest at full gate, is 10 848 cu. ft. per sec. This would give a total spillway capacity of $10\,848 \times 58$ (number of 38-ft. openings) = 629 184 cu. ft. per sec. Furthermore, if two or more gates were open on both sides of any discharging opening, this condition would increase the capacity of the latter slightly. There is a limit no doubt to this increased discharge effect by opening more gates. Perhaps the effect would not be appreciable beyond two, but, regarding this limit, no information on which calculations can be based, is available.

### Comparison Between Florence Gauge Rating and Wilson Dam Spillway Gate-Opening Rating

The United States Geological Survey gauge at the Florence (Ala.) Bridge is located about 3 miles down stream from the Wilson Dam. This offers an opportunity to make comparative calculations of the Tennessee River discharge. The Florence gauge was established in 1871 and a rating curve has been used for it since 1894. The control at the section is considered practically permanent. On this rating curve appear approximately 120 points indicating current-meter measurements taken from a range of 8 000 to 319 000 sec-ft.

For the purpose of comparison, data were taken from the records of the plant at Wilson Dam over a period such that the discharge ranged from 19 000 to 345 000 cu. ft. per sec., using twenty-four different flows within this range. These data included: (1) The setting of each of the fifty-eight spillway gates; (2) the trash chute opening; and (3) the quantity of water passing through the turbines based upon power-discharge curves. From these data, the total discharge of the river was determined, using the foregoing rating for the spillways (see Fig. 7). The Florence gauge discharges were taken from the official river records for the exact time when the recorded flows at Wilson Dam reached the gauge. Points were selected only when the gauge showed a constant reading for six hours. This allowed ample time for travel between the stations.

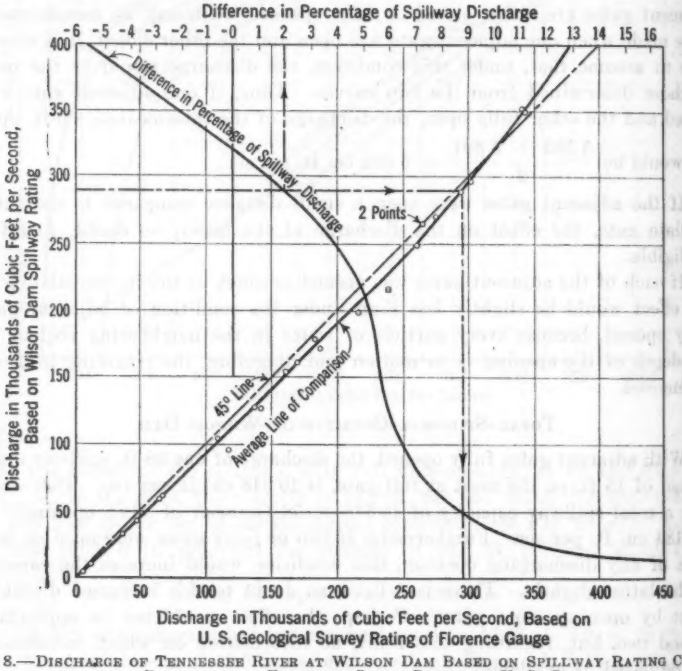

FIG. 8.—DISCHARGE OF TENNESSEE RIVER AT WILSON DAM BASED ON SPILLWAY RATING COMPARED WITH DISCHARGE AT FLORENCE GAUGE BASED ON U. S. GEOLOGICAL SURVEY RATING.

The data for the spillway computations are shown in Table 2. These discharges were listed in Table 3 and were added to the discharges through the turbines and trash chute, thereby giving the total flow past the dam. The official gauge heights and discharge rating of the Florence gauge are also included in Table 3 for purposes of comparison.

It will be noted that in all but the last two instances the discharge as shown by the Florence gauge rating is greater than that by the spillway

TABLE 2.—DISCHARGE MEASUREMENTS OF TENNESSEE RIVER AT WILSON DAM.

rating. The discharges in Columns (2) and (3) of Table 3 were deducted from those in Column (6) and the net quantities were plotted against corresponding values in Column (1), to give the average relation line as shown on Fig. 8. By drawing the 45° line, which would be the locus of all the points if the two methods checked exactly, it will be seen that the actual average relation line is below the 45° line from zero to 320 000 cu. ft. per sec., and there it crosses

and remains above it. Calculating the ordinate intercept between these two lines in percentage of the spillway discharge and plotting this percentage to the latter quantity, gives the compound curve marked, "Difference in Percentage of Spillway Discharge", part of which is negative and part positive.

| 348 628 | 890 | 2 285 | 351 803 | 26.51 | 346 000 |
| 350 516 | 890 | 561 | 351 967 | 26.35 | 343 100 |

To illustrate its use in comparing the two sets of data, consider a spillway discharge of 290 000 cu. ft. per sec. A horizontal line from 290 intersects the percentage curve at 2, so that the corresponding discharge, determined by the Florence gauge rating, would be $290\,000 + 0.02 \times 290\,000 = 295\,800$ cu. ft. per sec. This value may be checked by producing the horizontal line to intersect the average curve of comparison. The example here given excludes consideration of discharges through trash chute or turbines which must naturally be added to the quantity resulting from the use of Fig. 8.

ACKNOWLEDGMENT

This study of spillway discharge was made possible only by the generous interest and co-operation of Capt. Hugh P. Oram, Corps of Engineers, U. S. Army, District Engineer, Florence, Ala., who authorized both the time of the personnel and the use of equipment necessary for making the tests.

## DISCUSSION

CECIL E. PEARCE,[2] ASSOC. M. AM. SOC. C. E. (by letter).—As the author states, there are relatively few data in regard to flows through large spillways as deep as 18 ft. When spillways are designed for such heads, one might, in calculating the discharge of a large rounded ogee spillway section, use a conservative value, say, $c = 3.4$, and hope that the spillway would discharge at least as much as computed by using that coefficient in the formula:

$$Q = c\, L\, H^{\frac{3}{2}} \qquad (5)$$

Therefore, when such measurements as those presented by the author appear, engineers who are interested immediately greet them "with open arms" and analyze them to see if there are data which may be of use to them.

The writer does not agree with the author in his mathematical treatment of "Discharge Capacity of Spillway with Adjacent Gates Open." Mr. Puls has stated that "this increase in quantity discharged can be treated as if it were due to an increment of head."

It seems more logical to the writer to attribute the increase in discharge due to adjacent gates being open as caused by a lessening of the end contractions, because it can easily be seen that with only one gate open, the water would flow diagonally into the spillway opening, as well as straight into it. This would tend to cause more end contraction than when the adjacent gates are open and the water is flowing more nearly straight through the several spillway openings. If that is correct reasoning, the relation between $Q$ (one gate open) and $Q'$ (adjacent gates open) depends upon formulas having to do with end contractions. Regarding end contractions, Hoskins[3] states:

"Francis concluded that each contraction decreases the effective length of the weir by an amount proportional to $H$, and gave the following formula:

$$Q = 3.33\,(b - 0.1\,n\,H)\,H^{\frac{3}{2}}$$

in which ($n$) is the number of end contractions, usually two."

Other authors such as King[4] and Gibson[5] also cover the same subject, stating in effect that nothing better has yet been found, and that the formula seems to be rational.

Quotations from these and other authorities will not be made herein, but are mentioned for the purpose of showing that, from the best information available on the subject, the discharge does not change in proportion to the three-halves power on any value of $\left(\frac{H}{H + \Delta h}\right)$, but end contractions diminish the discharge from $Q$ (without end contractions) to an amount equal to $\left(\frac{L - n\,k\,H}{L}\right) Q$.

---

[4] "Handbook of Hydraulics", Horace W. King, First Edition, p. 67.

[5] "Hydraulics and Its Applications", A. H. Gibson, Second Edition, pp. 141–142.

It is thus seen that the change in discharge is not even proportional to $H$, but for any given values of $H$ and $L$, it is a constant with $L$ in the denominator, such that if $L$ is large enough, the change occasioned by end contractions is small in proportion to the total. For these reasons, the writer believes that Equation (4) does not correctly show the relation which exists between $Q$ and $Q'$.

The author also states that "the discharge, $Q'$, can be found because all other values are now known." Even if Equation (4) were correct, the absence of any mention of any measured value of $h_3$ leads one to believe that the author has assumed that $h_3 = h_1$ and calculated $Q'$ accordingly from Equation (4), obtaining 10 848 sec-ft. The writer believes that it is not necessarily correct to assume $h_3 = h_1$ in the case of gate fully open, and, therefore, $h_3$ and $Q'$ are both unknown; so that for any correct solution based on experiment, the value of $h_3$ should also have been measured. However, even if the value of $h_3$ had been measured, it is believed that Equation (4) is irrational and could not be expected to give rational results.

The derivation of Equation (4) implies that $Q'$ is to be calculated from it; otherwise, it has no use. Hence, it is assumed that $Q'$ was calculated and not obtained from actual measurement of velocities over the entire section, and that, therefore, the value, $Q' = 10\,848$, cannot be used as a check on Equation (4).

If the author's presentation is correctly understood, the writer believes that insufficient data are presented for any reasonably accurate calculation of $Q'$ (gate fully open) which could purport to depend on the field observations; or, at least, if sufficient data do exist, the mathematical presentation given by the author does not solve the problem.

The author's determination of $c = 3.420$ for one gate open, however, is as nearly correct as the data warrant, and for conditions similar to those at the time of measurement at Wilson Dam, the value of $c$ found ought to be fairly reliable.

The writer believes that the velocity of approach should receive more attention, in general, by all investigators, in order to make the results of observation and tests of more general value. For instance, it is fairly obvious on looking at the photographs of Wilson Dam,[6] that, with all gates open, in even so large a river as the Tennessee, the velocity of approach is of some importance, whereas in a large reservoir behind a dam, say 300 ft. high, it is almost negligible. Therefore, the data obtained at a site such as the Wilson Dam do not afford information for the engineer building a high dam, although the individual gates (possibly only five or ten of them in this case), and the general shape of the weir are almost identical with the gates where the tests or observations have been made.

Although it is realized that, in some cases, the problem is difficult, yet it is thought that an attempt should be made to reduce and refer all coefficients to a "standard" or still-water condition.

The author, by the use of his "vertical velocity" and "vertical velocity area" curves, and his method of attack in integrating the area under the ellipse, has

[6] "The Design and Construction of Dams," by Edward Wegmann, M. Am. Soc. C. E., Eighth Edition, p. 630.

shown considerable ingenuity, and has presented the data very clearly and simply. He also deserves commendation for making the data which he has collected available for others.

J. H. JONES,[7] ESQ. (by letter).—Whether or not one agrees with the conclusions drawn it is always an instructive pleasure to read a carefully executed investigation, and the equally careful analysis, such as Mr. Puls has made.

In carrying out his velocity measurements on such deep streams he has placed all hydraulic engineers in his debt, and British engineers who have few opportunities of dealing with large volumes of water find such researches especially valuable.

This discussion is not intended to present criticism, but is an alternative means of attack which may be of interest. The method has been crudely suggested in some notes by the writer, entitled, "The Standing Wave."[8]

Briefly, it consists of a denial of the usual theory, that, in the discharge through a large orifice, the velocity of any filament at a distance, $z$, below the free surface (see Fig. 4) is proportional to $\sqrt{z}$. Throughout the full depth at the *vena contracta* the velocity is sensibly uniform and proportional to $\sqrt{h_2 - cD}$, in which,

$h_2$ = depth from free surface to bottom of orifice.
$c$ = coefficient of contraction.
$D$ = depth of opening of gates (orifice).

The *vena contracta* is considered, since only there is the velocity of all filaments purely axial. Hence, the discharge from an orifice of length, $L$, depth, $D$, and with a head, $H$, is:

$$Q = c\,D\,L\,\sqrt{2g\,(H - c\,D)} \qquad (6)$$

TABLE 4.—COMPARISON OF DISCHARGE COMPUTED FROM TWO EQUATIONS.

| $D$, in feet. | $Q$, IN CUBIC FEET PER SECOND. | |
|---|---|---|
| | By Equation (3). | By Equation (6). |
| 1 | 726 | 785 |
| 2 | 1 474 | 1 540 |
| 3 | 2 202 | 2 260 |
| 4 | 2 952 | 2 960 |
| 5 | 3 692 | 3 630 |
| 6 | 4 404 | 4 255 |
| 7 | 5 076 | 4 860 |
| 8 | 5 692 | 5 450 |
| 9 | 6 308 | 5 980 |
| 10 | 6 978 | 6 460 |
| 11 | 7 657 | 6 930 |
| 12 | 8 378 | 7 350 |
| 13 | 9 130 | 7 760 |

The value of $c$ is difficult to establish, but, in a sluice-way with a horizontal bed, it does not differ greatly from two-thirds. However, in the present case, because of the distortion caused by the blunt piers, 0.62 is the value used. Solving Equation (6) for various openings, $D$, under a constant head, $H = 18$ ft., on a 38-ft. gate-opening, the results are as listed in Table 4.

[7] Chartered Civ. Engr., Kilmarnock, Ayrshire, Scotland.

[8] *Engineering*, August 10, 17, and 24, 1928; see, also, "Notes on Sluice-Gate Discharge," *Engineering*, September 29, 1929.

It will be noted that these only differ appreciably from the values obtained by Mr. Puls in Table 1, for the highest values of $D$; but here the reduction in $c$, due to the piers and grooves, is least, the *vena contracta* is less definite, and the values of $Q$ are thus greater than those calculated.

The writer has had the opportunity of seeing some German experiments which appear to confirm the fact that the value of $c$ in Equation (6) tends to increase slightly as the gate-opening increases. This would have the effect of increasing the value of $Q$ at the larger openings, bringing it into still closer agreement with the readings of the gauge.

It would appear that the sign and nature of the deviation of the writer's calculated discharges from those of Mr. Puls' formula, agree closely with the deviations shown by the readings on the Florence gauge.

Those who have facilities for sluice-gate measurements should try out this method as a check, so that engineers may possibly, as the information accumulates, be able to form some method of correlating values of $c$ with the detail design of sluice-ways.

Louis G. Puls,[9] Assoc. M. Am. Soc. C. E. (by letter).—The discussions of this paper manifest the keen interest of two engineers on the subject of spillway discharge. Their responses and inquiries are, no doubt, in the minds of many others. The writer does not deny the possibility of errors in the paper. There surely must be some, solely because it treats of quantities representing water discharge. Who can say truthfully how much water is flowing? Any treatise on the subject that departs from the old-fashioned "tin-can method" is surely destined to draw criticism. The paper was presented in a pioneer effort to supply a missing chapter in hydraulic science. Further investigation is needed, and it is to be hoped that others will venture into the field.

In regard to Mr. Pearce's discussion of the discharge with adjacent gates open, the writer wishes to emphasize that no effort was made in the paper to express a general law for the increment of discharge due to the influence of motion of the neighboring water mass. Referring to Fig. 2 it will be noted that two velocity measurements were made with adjacent gates closed. It should be stated that the increase is due to the reduction of end contractions or any other influences. In passing, it may be well to advance the theory that the elimination of friction between the water trains approaching the crest has a greater influence than the change of contraction between the two piers. No attempt was made in the paper, however, to invade the opinions or laws advocated by older authorities. The writer measured the increment of velocity at the depth stated and it is perfectly permissible to calculate the increment of head that would cause this velocity. Furthermore, it is logical to apply it as effective over the entire discharge area because, if any increment of head will increase the velocity at a point 2 ft. above the crest, it may also be expected to increase the velocity at higher elevations truly according to the fundamental law of falling bodies.

Mr. Jones has advanced an analysis that is commendable in its tendency to express a simple and usable law.

# COMPLETION OF MOFFAT TUNNEL OF COLORADO

By Clifford Allen Betts,[2] M. Am. Soc. C. E.

With Discussion by Messrs. J. Vipond Davies, R. H. Keays, A. A. Eremin, and Clifford Allen Betts

Synopsis

The 6.2-mile Moffat Tunnel through the Rocky Mountain Continental Divide, 50 miles west of Denver, Colo., was officially opened to railroad traffic on February 26, 1928.

The story of its conception many years ago and of the struggles since 1902 leading to its ultimate accomplishment has attracted widespread attention and has given the undertaking an unusually dramatic background. Difficulties encountered during construction due to caving ground and inflows of water led to the development of new tunneling methods which, combined with the unique Improvement District method of financing, added to the interest. Furthermore, the fact that this combination railroad and water tunnel embodied, at the time of its construction, the longest railroad tunnel in the Americas, in addition to a conduit of equal length, permitted the use of new and modern machinery and led to numerous refinements in standard equipment.

The history of the early stages of the work up to August, 1925, together with a discussion of the contract, has been published by the Society.[1] Inasmuch as that paper made no reference to the survey methods used in carrying alignment and grades over the range that rises to 12 000 ft. above sea level and 2 800 ft. above the tunnel, nor to the camps, these are described herein in some detail, together with other phases of the work which have developed subsequent to 1925.

[1] For a general description of the history, development, and progress of this undertaking to the summer of 1925, reference should be made to the paper by R. H. Keays, M. Am. Soc. C. E., entitled "Construction Methods on the Moffat Tunnel," *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 63. Published in April, 1930, *Proceedings*.

[2] Engr., U. S. Bureau of Reclamation, Owyhee Dam, Nyssa, Ore.

Soft ground encountered for a distance of 2½ miles in from the West Portal was the outstanding feature of the construction. The methods and machinery used to combat this obstacle, including the design of heavy timbering, steel reinforcement, concrete lining, and the use of the "Lewis Traveling Cantilever Girder" are among the tunneling developments described. Similarly, the notes on plant machinery and on costs of vital operations epitomize extensive studies.

Ventilation tests made at the Moffat Tunnel offered a unique opportunity for the correlation of data on air-friction factors for tunnels of mining size on which exhaustive information is available and on factors for standard railroad tunnels on which fewer tests have been made.

The construction of the Moffat Tunnel involved among other quantities (in round figures): 750 000 cu. yd. of excavation; 16 000 000 ft., board measure, of timber; 2 500 000 lb. of dynamite; 700 000 lb. of drill steel; 700 miles of drill holes; 28 000 000 kw-hr. of electrical energy; and 25 000 000 man-hours.

The final cost of work as shown by outstanding bond issues is $15 470 000, in addition to which approximately $2 000 000 revenue from camps, commissaries, interest on bank deposits, and other sources went into the work and into interest on the bonds during construction.

The ultimate object of the project is to make possible a transcontinental rail route through Denver; to insure adequate transportation facilities for Northwestern Colorado; and to provide an additional source of water supply for Denver and contiguous territory.

## Historical Résumé

*Early Surveys.*—When the final "holing through" blast, touched off by President Coolidge on February 18, 1927, broke down the 7-ft. granite barrier between the east and west headings of the Moffat Water Tunnel, it was said, as the Colorado and Utah officials joined hands, that this was the highest and lowest holing through of a tunnel in history; the highest because it was more than 9 200 ft. above sea level, and the lowest because the headings were 2 800 ft. below the crest of the Continental Divide.

For half a century this Divide, extending from the northern to the southern boundaries of Colorado, and beyond, had stood in the way of adequate transportation from the East to the West. A tunnel through the Rockies to provide a practical route had been first conceived in the early Sixties by Governor Gilpin when the Union Pacific Railroad Company began laying the first transcontinental track. It had been taken for granted that the route would pass through Denver, the largest center of the West. The late Grenville M. Dodge, Hon. M. Am. Soc. C. E., Chief Engineer of the Union Pacific Railroad, had surveyed all the passes from Laramie Canyon in Wyoming to the Arkansas River in Southern Colorado; but the unbroken barrier of the Divide rising to

12 000 ft. above sea level offered no suitable pass. On November 7, 1866, General Dodge's party barely escaped death in a blizzard near the site of the present East Portal of the Moffat Tunnel by turning their pack animals loose and going down the valley to the nearest camp on foot. This unfortunate experience did not show this site in a favorable light at the time, but eventually the process of elimination proved it to be the narrowest part of the Divide at an elevation suitable for railroading.

Surveys were run over this Rollins Pass again in 1867 for the Jefferson and Boulder County Railroad and Wagon Road and in 1869 by the Kansas Pacific Railroad Company. In 1880, a 2-mile tunnel site was surveyed and an open cut begun near Yankee Doodle Lake. This and some grading constitute the remaining evidences of the ambitious program of the Denver, Utah, and Pacific Railroad Company which, however, abandoned the work. Part of the grade was later acquired by the Chicago, Burlington, and Quincy Railroad Company, and in 1884-85 that Company ran surveys over Rollins Pass. A 3-mile and a 5-mile tunnel were projected; the east end of the latter being above and to the north of East Portal and the west end on Jim Creek west of James Peak.

*Moffat Road Surveys.*—Following this the Moffat Road ran ten lines in 1902, locating a 2.6-mile, a 4.1-mile, and a 5.8-mile tunnel. Plans went so far that bids were obtained on the 4.1-mile tunnel but, believing that the time required for construction would be prohibitive and that only the long tunnel would eliminate effectively the snow hazards, the road was built over Rollins Pass at Elevation 11 660, reaching Corona, Colo., on October 2, 1904. It was hoped that, pending construction of a tunnel, the scenic value of the line over the Rockies would compensate for the snow-fighting costs; but the advent of the automobile interfered, and the bitter fight against Nature forced the road into receivership by the time the Moffat Tunnel was begun in 1923.

David H. Moffat's historic fight against ruthless Nature and adverse railroad interests is an epic of vision, determination, and public-spirited generosity. His road reached Steamboat Springs on December 13, 1908, having cost $14 000 000 and later was extended to Craig, Colo. (255 miles from Denver).

## Construction

*Moffat Tunnel Surveys.*—The Moffat Tunnel Act authorizing the construction of the Moffat Tunnel provided no funds that could be used for preliminary investigations, such as diamond drilling and surveys, prior to the sale of bonds. Sufficient private funds were made available for preliminary surveys, however, and thus the old Denver and Salt Lake Railroad (Moffat Road) survey lines were re-established and monumented. Upon geological advice that it would be advantageous to shift the West Portal location about 400 ft. south and the East Portal 75 ft. north, new portal sites were located by offsets from the old line. Timber cuttings for the new line were then started while the tunnel was being extended into the mountain on the offset lines.

The surveys for the Moffat Tunnel crossed the Continental Divide at a storm-swept point 12 000 ft. above sea level. There the crest of the Rockies flattens out, forming a plateau ½ mile wide which effectively prevented sighting

toward each portal from a point on top. Consequently, it was necessary to establish three points on the Divide, so located that from the easternmost point the East Portal back-sight target could be seen (Fig. 1), while from the western point the West Portal terminal target was visible. These five points, forming the center line of the Water Tunnel, had to be placed in alignment at night because there was considerable refraction during daylight hours between the targets at elevations of 9 000 and 12 000 ft. This was attributed largely to the differing densities of the air and to temperature variations. Frequently, it exceeded 3 ft. on the 6-mile sight between the east terminal target and the Divide.

Lights placed behind paper or ground glass gave excellent results as sights especially after midnight when atmospheric conditions were most favorable. To permit accurate setting of points at night, a spirit-level head was mounted on a standard transit tripod with a painted metal target set vertically at one end so that a light could be placed behind and the target moved until it was on line. A hole in line with the pointed aperture of the target carried a plumb-bob string for setting points (using wind breaks). The final underground closure of 0.11 ft. after carrying the line 10 miles over the range and 6 miles underground substantiates the accuracy of this night work.

The line was carried underground through the Water Tunnel (which served as a pioneer bore), by setting up the transit on the terminal target, sighting on the skyline target on top of the Divide, depressing the telescope, and setting a point at the portal. From there the line could be carried in on special brass vernier bars, ¼ in. by 1 in. by 10 in., attached to plugs in the roof of the tunnel. These bars were accurately graduated in hundredths of a foot so that a brass vernier rider carrying a plumb-bob line could slide along the upper edge and permit readings to 0.0001 ft. These bars at about 500-ft. intervals not only made it easy to run independent lines and subsequently to compare the readings, but also facilitated adjustments where the ground and timbers were in motion. Caps moved several inches at points between 2 and 3 miles in from West Portal.

To determine the distance between portals a triangulation system was used, with a base line 3 756.587 ft. long, near West Portal, and eight stations on the mountains. Two U. S. Geological Survey, 300-ft. invar tapes having a coefficient of expansion of only 0.00000042 were used in measuring the base line, with corrections for sag and temperature. Supplementing the triangulation, slope measurements were made over the mountain with a 500-ft. chain, thus locating the profile. The horizontal distance through the tunnel was 1.75 ft. shorter than that computed.

Precise levels were run over the center line between the portals. These checked previous grades run independently over the Divide *via* the survey clearing and the Denver and Salt Lake Railroad tracks (31 miles). The grades checked within 0.345 ft. on holing through and were readily adjusted in the remaining enlargement (5 523 ft.).

Cross-sections of the Railroad Tunnel were taken with a "sunflower", mounted on a tripod, which consisted of a vertical aluminum disk graduated in degrees, beginning with zero at the top. Pivoted at the center was a rotating arm upon which a measuring rod could be placed to show simultaneously

the distance and angle to a point on the tunnel wall. From the known positions of the "sunflower", sections could be plotted rapidly.

*Work Begun by Commission.*—Ground was broken for the Water Tunnel on August 25, 1923, following the decision of the United States Supreme Court validating the Moffat Tunnel Improvement District Law of May 12, 1922, whereby the Improvement District, of 9 000 sq. miles, including Denver, was created. Through its elected officers, the Moffat Tunnel Commission was empowered to assess real estate in the District, issue bonds, construct a railroad and water tunnel, and administer them when finished. This Colorado law provided for the making of contracts, not exceeding 99 years in duration, for the use of the tunnel up to the limits of its capacity for rail and water transportation as well as for power, telegraph, and telephone lines, at the same time prohibiting any monopoly or the sale of the property.

Pending the letting of a contract and in order to have the pioneer tunnel underground before the deep snows indigenous to the 9 000-ft. elevation arrived in October, the Moffat Tunnel Commission rushed the construction of camps at both East and West Portals. When a contract was awarded to Hitchcock and Tinkler, Incorporated, on September 20, 1923, the camps were under roof, the West Portal Water Tunnel had been driven in 32 ft., and the open cuts were well advanced.

*West Portal Camp.*—Both East Portal and West Portal camps were constructed in 1923 while machinery was being delivered and the excavation of the tunnel started. The camp sites were so different in appearance that it was frequently said that the portals hardly seemed to be in the same mountain. This difference persisted as the headings extended underground. West Portal, the first camp completed, was surrounded by heavily timbered slopes beneath which lay the soft rock of an extensive fault zone, while East Portal had more barren and precipitous surroundings (Fig. 1), showing the solid gray granite which extended to the center of the Divide.

While the camp site at West Portal was being cleared of heavy pine, and the buildings were being constructed, the men were quartered at Wood's saw-mill near-by. The water supply for this site was taken from Buck Creek and piped by gravity to camp and plant buildings, provision being made for fire hydrants in the camp streets. Large septic tanks were used for the sewerage system. The ten 30-man bunk-houses, 20 by 50 ft., with rooms accommodating two men each and allowing 250 cu. ft. of air per man, were built 75 ft. apart to reduce the fire hazard.

These houses were wired for electric lights, heated by pipeless hot-air furnaces, and built with paper between the inside and outside sheetings. A building was provided for the Moffat Tunnel Commission Engineering Staff and one for the Contractor's organization. Later, these were augmented by eight 4-room cottages for engineers and foremen with families and by twenty-two 2-room cabins for miners with families, preference being given by seniority. The cottages rented for $25 per month and the cabins for $15, which practically amortized the cost of construction. Many families lived in privately owned houses near the portal camps.

A mess hall seating 250 and serving as many as 40 000 meals per month, at a cost of about 42 cents each, was constructed between the bunk-houses and the

FIG. 1.—EAST PORTAL, MOFFAT TUNNEL, LOOKING WEST FROM BOULDER CREEK. CAMP BUILDINGS IN CENTER AT FOOT OF MOUNTAIN. PARALLEL MARKS OF SURVEY LINE APPEAR STRAIGHT AHEAD FROM WOODED SLOPE.

FIG. 2.—TYPICAL RAILROAD TUNNEL THROUGH GRANITE, SHOWING EQUIPMENT. LATER, 36-INCH GAUGE TRACKS WERE REPLACED BY BALLASTED STANDARD SINGLE-TRACK LINE.

portal, as was also a recreation hall containing a commissary, post office, reading room, pool hall, and auditorium which could be used for dances, prize fights, moving pictures, and other entertainments for which the camp gained a reputation. In fact, East Portal and West Portal, with about 500 workmen at each, ranked with some of the largest communities along the railroad in money spent during the five years of bustling activity before construction ceased and they became "ghost cities".

The laundry, equipped with rows of stationary tubs, shower baths, toilets, and plenty of hot water, was the central wash house, there being no tubs in camp. As a preventive of pneumonia, which at that altitude is pernicious, a change house was built at each portal with lockers and showers so that workmen coming off shift could enter the building and change to dry clothes before going out into the cold. Wet clothes were attached to wire rope hoists and raised out of reach overhead to dry, the free end of each rope being secured inside the owner's locker.

Grade schools accommodating 60 pupils were provided for the camp children at each portal. The Moffat Tunnel Commission furnished the buildings, and the County School Districts, the teachers.

*East Portal Camp.*—The camp at East Portal (Fig. 1) was planned similar to the West Portal camp, except that the rocky ground led to the installation of individual septic tanks for the houses instead of ditching for sewers to a central disposal plant.

*Plant Buildings.*—The plant buildings at each portal were grouped closely around the portals and connected to the Water Tunnel by snowsheds so that the severe winter weather, that frequently extends into June at this locality, would not handicap operations.

A steel sharpening shop opened directly off the tunnel. Beyond this was the machine shop with lathe, drill press, grinders, welding outfits, and all tools required for large or small repair work.

The power house received 2 300-volt current transformed from the 44 000-volt, 3-phase, 60-cycle transmission line from the Boulder Canyon Plant of the Public Service Company of Colorado. Power consumption was planned to keep the maximum demand as low as possible, usually about 1 800 h.p., with the result that the cost averaged 1 cent per kw-hr. for a total use of about 28 000 000 kw-hr.

Comparatively few power interruptions occurred on the power line to East Portal, but the 7-mile line between portals, over the Continental Divide, required considerable maintenance during winter months. Tubes of ice formed on the wires by snowdrifts and sleet storms and then, swayed by the high gales, broke off insulators or poles. This usually occurred at the highest part of the line where iron wire replaced copper for strength. On one occasion a Mexican laborer tripped across a section of the power line that was buried in snowdrifts and was burned beyond recognition.

Adjacent to the power house was the electricians' shop and the battery recharging station for the storage batteries used on the 4-ton locomotives. The warehouse, primer house, and carpenter shop were grouped near-by.

At West Portal a timber-framing shed was equipped not only with the usual cut-off and band-saws but also with a timber dapping machine consisting

of a dado-head saw that could be drawn across the timbers, cutting to desired depths and widths.

Among the items included in the plant list used in advertising the machinery for sale at the conclusion of the job were the following, with their costs, f. o. b. job:

| | |
|---|---|
| Rolling stock | $213 171.00 |
| Air shovels and mucking machines | 62 573.50 |
| Drills | 53 541.08 |
| Concrete mixers and pneumatic placing machine | 25 653.83 |
| Lewis girders | 26 782.00 |
| Motor generator sets | 20 848.96 |
| Pumps | 8 612.00 |
| Blowers | 14 279.00 |
| Equipment in shops and power houses | 103 000.00 |
| Miscellaneous electrical equipment | 12 000.00 |
| Hoists and jacks | 11 795.67 |
| Rail | 30 180.00 |
| Wire | 54 322.00 |
| Pipe | 58 134.89 |

The "Inventory of Plant Machinery, Camp Buildings, and Equipment" showed a summary of:

| | |
|---|---|
| Total plant machinery | $739 499.01 |
| Total camp buildings (East Portal) | 100 096.48 |
| Total camp buildings (West Portal) | 124 926.18 |
| Total camp equipment (East Portal) | 13 200.00 |
| Total camp equipment (West Portal) | 15 800.00 |
| | $993 521.67 |

*Geological Conditions Encountered.*—From the beginning the ground at West Portal presented difficulties. The East Portal headings, on the other hand, passed through comparatively uniform grey metamorphic granite (Fig. 2), with some quartz monzonite and injection gneiss seams of consistently similar dip and strike. In all, there was less than 1 500 ft. of seamy ground requiring support east of the apex and at no place were the pressures great. This was the character of formation on which the plans were predicated.

It is interesting to note that this end of the tunnel was completed six months ahead of schedule and practically within the original estimate. The semi-annual financial statement of the Moffat Tunnel Commission of January, 1925, before costs had been greatly increased by the unforeseen difficulties, showed the cost of excavation in the headings to be $10.41 as compared with $17.00, the contract price; and the cost of enlargement excavation, $4.80 as compared with $4.70 bid. (See Appendices I and II.)

The fact that the east headings overcame the half-mile lead that the West Portal had acquired by starting first and eventually made a mile greater progress indicates the difference in rock at the two ends. Furthermore, nearly twice as much dynamite per yard (11 lb.) was required for the East Portal rock as for that at West Portal.

Geologists had predicted less than 2 000 ft. of questionable rock that might require support; no funds had been allowed for preliminary diamond drilling. As a result the 2½ miles of fault zone with seams and dikes not only increased

the cost of the project, but required more time, as is graphically shown on the progress chart, (Fig. 3). Subsequent geological studies made from the bore within the mountain indicated that the hidden fault zone, which caused the shattered rock at West Portal, extended for such a long distance along the Divide that to have avoided it by shifting the tunnel location would have been impractical.

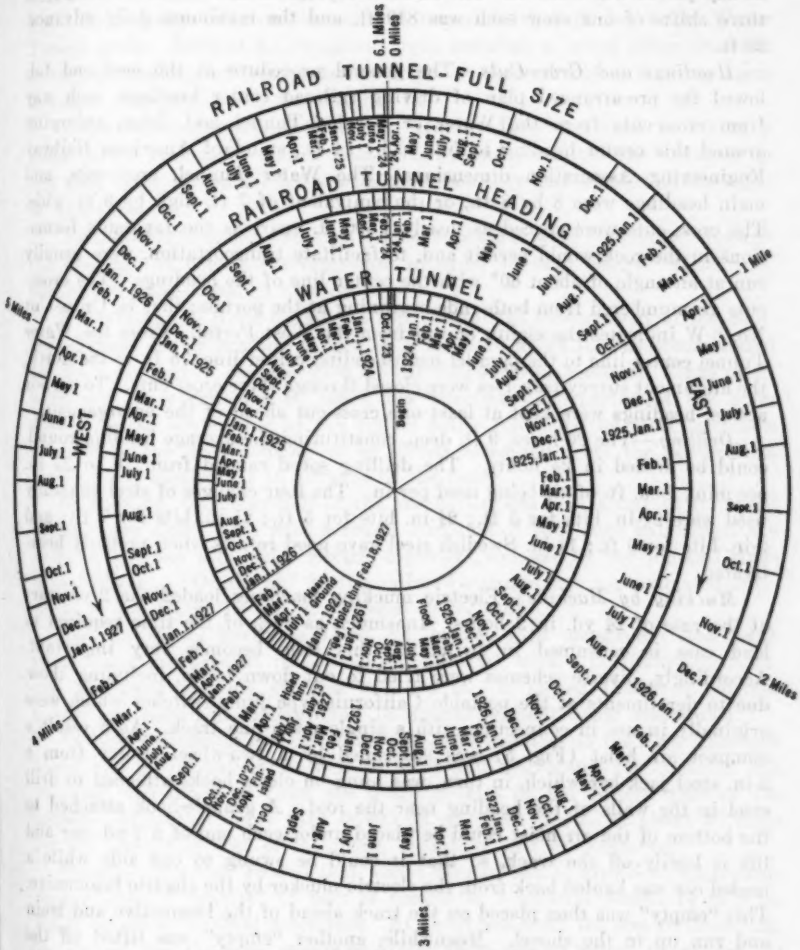

FIG. 3.—PROGRESS CHART, MOFFAT TUNNEL.

## Operations at East Portal

*Twin Heading System.*—At East Portal a system of alternating was established whereby the same crew could drill first the Water-Tunnel heading and

then, while that was being mucked out after shooting, could move over to the Railroad-Tunnel heading and proceed to drill there without interfering with the mucking crew. In this way three shifts of about seventeen men each could usually drill, shoot, and muck three 8-ft. rounds in 24 hours, or a full round each shift. Under this system the maximum advance made during a 30-day period was 1 583 ft. The maximum progress in a single heading with three shifts of one crew each was 849 ft. and the maximum daily advance, 33 ft.

*Headings and Cross-Cuts.*—The general procedure at the east end followed the pre-arranged plan of driving railroad center headings each way from cross-cuts from the Water or Service Tunnel and, later, enlarging around this center heading to full 16 by 24 ft., standard American Railway Engineering Association dimensions. The Water Tunnel, cross-cuts, and main headings were 8 by 8 ft., or the equivalent of 7 ft. high by 9 ft. wide. The cross-cuts were spaced as nearly 1 500 ft. apart as the favorable formations in the rock would permit and, to facilitate transportation, were usually run at an angle of about 60° with the center line of the headings. The cross-cuts are numbered from both ends beginning at the portals; that is, Cross-Cut No. 8-W indicates the eighth one in from the West Portal. From the Water Tunnel center line to the parallel main-heading center line, 75 ft. to the north, the alignment survey traverses were closed through these cross-cuts. To permit access, headings were kept at least one cross-cut ahead of the enlargement.

*Drilling.*—The 26 holes, 9 ft. deep, constituting the average heading round, could be drilled in 2½ hours. The drilling speed ranged from 10 to 25 in. per min., 1 cu. ft. of air being used per in. The four changes of steel generally used were 2⅜-in. bits for 3 ft.; 2½-in. bits for 5 ft.; 2⅝-in. bits for 7 ft.; and 2-in. bits for 9 ft.; 1½-in. Swedish steel gave good results when properly heat-treated.

*Mucking by Machine.*—Electric mucking machines loaded the 2-yd. cars at the rate of 24 yd. in 2 hours. Inasmuch as 60% of the time required to load cars is consumed in switching, this item becomes very important. Accordingly, diverse schemes were tried to cut down losses, including those due to derailments at the portable California-type jump-switches which were originally in use in connection with a single main-line track. As a result a compact air hoist (Fig. 5) was suspended by a two-wheel trolley from a 3-in. steel jack bar which, in turn, was hung on clevis hooks attached to drill steel in the walls of the heading near the roof. A grapple-hook attached to the bottom of the air hoist could be placed under each end of a 2-yd. car and lift it bodily off the track, so that it could be swung to one side while a loaded car was hauled back from the electric mucker by the electric locomotive. This "empty" was then placed on the track ahead of the locomotive and train and run up to the shovel. Meanwhile, another "empty" was lifted off the track and set over out of line ready for a repetition of the operation, until the entire train was loaded. This switching was done about 200 ft. back from the face. Locomotive attendance, essential to this speedy switching system, was required by the grades anyway, so in this case it was not chargeable to this system of switching.

*Hauling.*—The high-sided 2-yd. cars used on the 24-in. track (40-lb. rail) in the headings were suitable for machine loading and not adapted to hand mucking. In order to relieve these cars of the long trip out on the dump and to release them for the many heading operations which sometimes numbered twenty or more and made heavy demands upon transportation, transfer docks were provided where muck from the narrow-gauge cars could be dumped into the 4-yd., 36-in. gauge cars on the railroad tunnel level, 8 ft. below the Water Tunnel grade. Sidings for "empties" were installed at every other cross-cut so that dispatching of transportation might be more flexible. Hauling costs increased perceptibly with the distance in.

*Underground Accommodations.*—A "Harvey House" (lunch room) in a niche in the rock more than a mile underground permitted the workmen to rest after being served hot coffee with the lunch they had selected and brought in with them.

"Drill doctor" benches and electricians' cupboards were distributed through the headings at convenient cross-cuts in order to save delays. Mine telephones were also installed at cross-cuts.

*Enlargement in Hard Rock.*—At East Portal the enlargement of the Railroad Tunnel center heading from 8 by 8 ft. to 16 by 24 ft. was accomplished for the most part in one operation by the ring-shooting method. Rings of 27 holes each were drilled 4 ft. apart, the direction and spacing of the holes normal to the center line of the tunnel being controlled by steel templates attached to the drill housing or by offsets measured from the center line. Drilling was carried far in advance of the bench.

In shooting, the lower half of the excavation was kept about 16 ft. ahead of the upper ring. As a rule, a round consisted of two lower half rings, one without, and one with, delay electric exploders, followed by two top half rings with "delays". "Overbreak" in the railroad enlargement approximated 20%, while, in the Water Tunnel, it averaged 50 per cent.

The air shovel having a 1½-cu. yd. bucket with manganese steel teeth consistently averaged 24 ft. per day (two shifts), with a maximum of 53 ft., and maximum monthly progress of 1 002 ft. It moved 11 000 cu. yd. per month and remained underground 18 months without being overhauled.

In 1925, a crushing and screening plant was installed on the East Approach dump and 2½-in. ballast as well as sand and aggregates for concrete and "gunite" was produced from the tough granite in the eastern part of the tunnel. Altogether, more than 66 000 cu. yd. were treated at about 50 cents per yd., including cost of the plant, operation, and maintenance.

*Gunite.*—Through ground that would decrepitate, or air-slack, upon exposure, a coat of "gunite" (1 part of cement to 3 parts of sand), 1½ to 3 in. thick, served as an ideal protection. At about one-tenth the cost of timbering, it accomplished the same results providing there was no weight to support. It was particularly valuable over diagonal seams that might wash out and release blocks of rock after the air had softened the seam. Such spots would require a long stretch of timbering, whereas the gunite could be applied locally.

Beginning in 1925 gunite was used extensively covering thousands of square feet of rock surface at a cost for a 2-in. coat of 7 cents for labor plus 8 cents for material, or $8 to $14 per lin. ft. of tunnel as actually placed. About 20 000 sq. ft. was a good month's work. Much of the rock east of the apex was thus protected, only about a mile being left exposed.

*Water Inflows.*—Water was the greatest handicap encountered at East Portal. On February 18, 1925, a water seam was cut in the Water Tunnel 8 050 ft. in from East Portal.[3] This connected directly with Crater Lake, 1 300 ft. above, and produced 1 800 gal. per min. until silt from the lake bottom clogged the seam. Again, in October, 1925, water seams were encountered, which produced several hundred gallons per minute and materially retarded progress. As new seams were cut, the back seams would dry up, so that the headings, which were then on the down grade beyond the apex (Station 2536+54), required pumps.

The main seam 1 800 ft. below Ranch Creek was tapped on February 28, 1926. The "graveyard shift" coming in to muck out the heading hung up their electric light cluster and returned to Cross-Cut No. 10-E, 300 ft. back, for tools. When they returned to the heading it was noticed that the lights had apparently been moved. By this time the water, which had entered from below the muck-pile and had been slowly moving it with respect to the lights, burst through. It carried the pile 20 ft. down the tunnel and brought in 900 yd. of fine materials which were strewn for 200 ft. down the track.

The mucking machine and tools were moved to Cross-Cut No. 10 before the water reached the waists of the men, who then retreated to the apex 1 250 ft. away and installed pumps. Meanwhile, the water ran through the cross-cut and down to fill the Water Tunnel heading. Within five hours both headings were filled and water started to flow eastward over the apex through the Water Tunnel, the Railroad Tunnel having been dammed with sand-bags to protect enlargement work there. When the water reached Cross-Cut No. 8, it was diverted into the Railroad Tunnel east of the bench operations.

For a time a weir built at Cross-Cut No. 8 registered 2 500 gal. per min. and the tracks were covered with water, interfering with the electric locomotives; but within a week, the flow having subsided to 1 500 gal. per min., the headings were unwatered and work was resumed. In unwatering the headings, pumps and pipe were mounted on flat cars (Fig. 4) and backed toward the water, pumping under heads as high as 10 ft. From March 8 to April 8, the flow was 1 500 gal. per min.; in May, the flow decreased to about 600 gal. per min., which had to be pumped until the headings were holed through in the Water Tunnel and the benches completed in the railroad bore.

Other flows, totaling 450 gal. per min., were intercepted between Cross-Cuts Nos. 13 and 14. These were in looser rock and had the effect of softening the adjacent ground, thereby interfering not only with the holing through of the headings, but also with the excavation of the last 100 ft. of bench, which happened to come near the same location.

[3] "Construction Methods on the Moffat Tunnel," by R. H. Keays, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 68.

FIG. 4.—UNWATERING HEADING. PIPE LINE DISCHARGING AT APEX. WHENCE WATER FLOWED BY GRAVITY TO PORTAL.

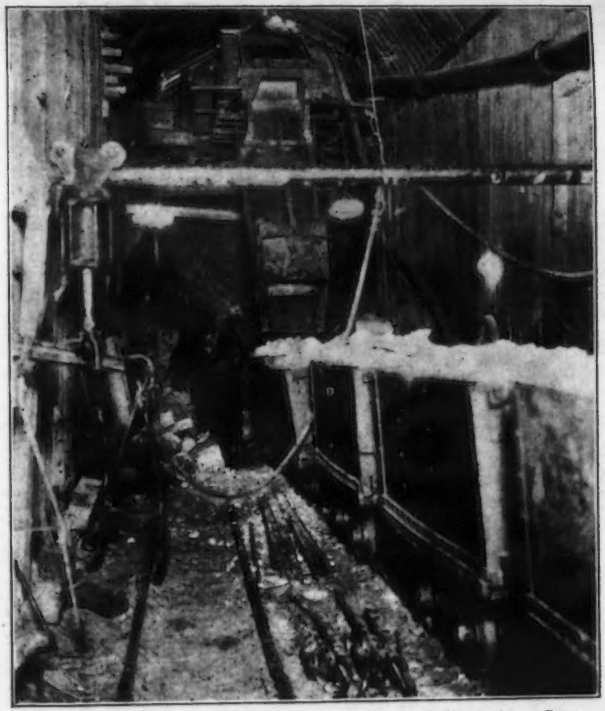

FIG. 5.—OPERATION OF LEWIS GIRDER DISCHARGING MUCK INTO CARS. AIR-LIFT CAR SWITCHER SHOWN IN FOREGROUND.

At the completion of the tunnel a fairly constant flow of about 600 gal. of water per min. was leaving *via* the West Portal drainage gutters and about 30 gal. per min. out of East Portal.

## Operation at West Portal

*General Plan.*—At West Portal, the Water Tunnel functioned as a pioneer tunnel, advancing far ahead of the Railroad Tunnel enlargement so that heading, widening, and enlargement operations could be carried on simultaneously through the numerous cross-cuts. In this way as many as twenty attacks were made at different points at the same time, greatly expediting the work through the hazardous ground.

As at East Portal, all piping, wiring, and heading transportation were carried through the service tunnel, leaving the enlargement operations free of interference from these sources. The piping system included 7¼-in. casing for high-pressure air, 3½-in. water line, 12-in. ventilating line, and, in some places, pump discharge lines. The wiring provided for a 2 300-volt, 3-phase, 60-cycle, lead-covered cable supplying motor-generator sets at strategic points in the Water Tunnel; 250-volt direct-current wires for trolleys, mucking machines, and pumps; a 250-volt, 50-ampere "shooting" line; a 110-volt lighting line; and a telephone line.

Where pressures were encountered, top headings were followed by widenings for roof segments which, in turn, were followed by the excavation of the bench below the wall-plates either in one or two lifts. At some places west of the apex in rock that appeared solid, center headings were attempted and the Water Tunnel grades were accommodated to this 8-ft. change. However, such sections almost invariably required lining when opened up to the full size of the railroad bore. In changing from center to top headings, gradients as high as 5% were negotiated by the muck trains, but 2% was the maximum for machine mucking.

*Bench Excavation.*—The bench excavation presented the most difficult problems through the soft ground. Usually by the time the bench crew of fifteen men started work the large rock area had been exposed long enough to make it treacherous if it was not actually developing extreme pressure, tending to force in the side posts and allowing the roof to settle.

The cycle of operations on the bench ranged from 12 to 23 hours, as a result of which a "call shift" was instituted. The drilling of thirty to forty horizontal holes 20 ft. deep proved more satisfactory than drilling vertical down holes ahead in an attempt to save time.

*Loss of Life.*—During the early part of 1925 difficulties reached a crisis. At the same time that water was hindering progress at the East Portal, crushed, folded, and faulted rock was causing delays in the West Portal headings and widenings. Small cave-ins occurred in the headings and crushing wall-plates threatened to let down the roof timbers in the enlargement as unprecedented pressure developed.

One serious cave-in occurred in the Railroad Tunnel 175 ft. east of Cross-Cut No. 9 (2.3 miles from West Portal), on July 30, 1925, when six workmen of the day-shift timber crew were killed by 100 tons of rock that

fell without warning from the north side of the roof as timbers were being placed. Characteristic heroism was displayed by the miners who volunteered to a man for the rescue work which was organized in case any of the men were buried alive. The coroner returned a verdict of "unavoidable accident".

In all, twenty-eight men made the supreme sacrifice in putting through the Moffat Tunnel—a remarkable record considering the hazardous nature of the formations encountered.

*Lewis Traveling Cantilever Girder.*—In order to cope with the emergency the first Lewis traveling cantilever girder, originated by George Lewis, General Manager, was installed at the West Portal bench near Cross-Cut No. 2 in March, 1925. This invention (Figs. 5 and 6) had numerous advantages, foremost among which was mobility. Designed to support the roof timbers and wall-plates (as a cantilever resting on, and extending back from, the heading) while the bench was being excavated and posts were being set, this machine successfully held the weight and increased the speed of progress. It is valuable in soft-ground tunnels of large size and can be used for either heading and bench or pioneer tunnel operations.

Four of these girders were used on lined sections of the Moffat Tunnel extending two miles or more, and their effectiveness has been tested through soft running ground of slicken-sided schist and gneiss as well as through blocky granite. On one occasion, Girder No. 1 caught a cave-in, protecting the workmen beneath. After tons of muck had been removed, the long girders, which had been bent downward several inches at the end, returned to their original alignment.

Girder No. 2 installed in October, 1926, was equipped with a conveyor belt, 30 in. wide, operating at 30 ft. per min. by means of a 50-h.p. electric motor. Being reversible, this conveyor could carry muck from the heading back through the center of the girder and discharge it through a 14-ft. chute into 4-yd. cars behind the bench (Fig. 5), or it could carry timbers and supplies from the bench ahead to the headings. The other three girders were without conveyors inasmuch as they were used for benches where widening had been handled through cross-cuts ahead. A description of Girder No. 2 (Fig. 6), therefore, will cover the others.

Two plate girders, 42 in. deep by 65 ft. long, spaced 6 ft. apart with rigid cross-braces of structural angles, which also served as the frame for the conveyor rolls, constituted the backbone of the machine. Cross-arms extending at right angles to the center line of the girder and supported beneath it by steel stirrups could be moved out under the wall-plates and jacked tightly up against them, using 15-ton screw-jacks built with the hanger and operating through a lever and rocker-arm. There were twelve cross-arms at the rear, or bench end, of the girder to support the roof and four at the forward end to keep it in place against the up-thrust when the load was applied at the rear end. Jacks against the roof were sometimes used for the same purpose.

In addition to the twelve cantilever arms beneath the wall-plate there were two that rested upon the top of the wall-plate, converting the cantilever into

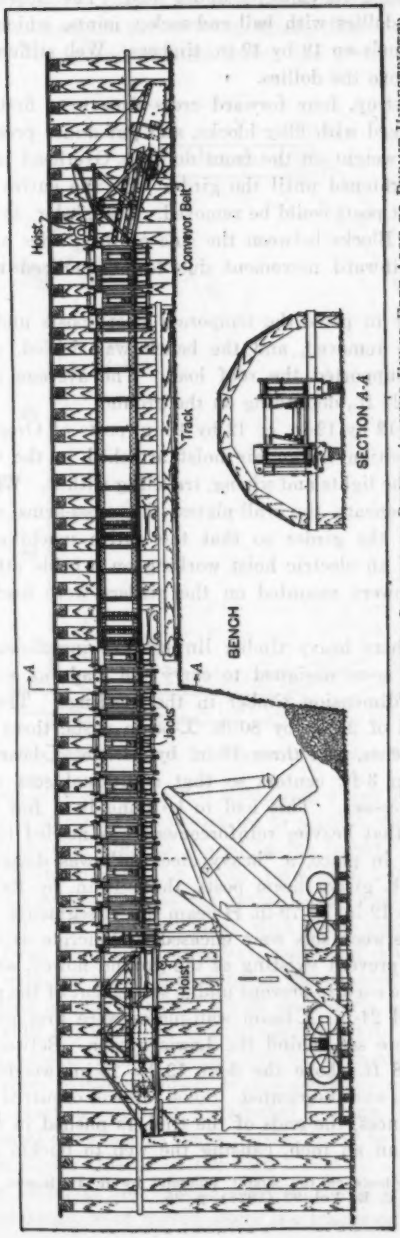

FIG. 6.—LEWIS TRAVELING CANTILEVER GIRDER: ELEVATION SHOWING SUPPORT ON BENCH, JACKING UNDER FREE ARCH TO PERMIT UNRESTRICTED MUCKING, AND CONVEYOR SYSTEM

a beam and increasing its capacity under load. The entire machine rode on two pairs of steel dollies with ball-and-socket joints, which traveled along a track of steel channels on 12 by 12-in. timbers. Web stiffeners reinforced the ½-in. web-plates above the dollies.

In making a set-up, four forward cross-arms were first rolled out under the wall-plate, wedged with filler blocks, and put under pressure by the jacks, thus throwing the weight on the front dollies. Overhead jacks or rear cross-arms were next tightened until the girder took the entire roof load so that the temporary short posts could be removed. The girder, as designed, weighed about 200 000 lb. Blocks between the side of the girder and the wall-plates counteracted any inward movement due to unequalized roof and side-wall loads.

With the girder in place the temporary short posts under the wall-plates at the bench were removed, and the bench was drilled, shot, and mucked while the girder supported the roof load. The average progress per shift varied from 12 to 24 ft., depending on the ground.

Following this, 12 by 12-in. or 12 by 18-in. posts of Oregon fir were pulled up into plumb position by an air hoist attached to the end of the girder (Fig. 6) and, like the lights and wiring, traveling with it. When these had been wedged in place beneath the wall-plates, the cross-arms were released and pulled back under the girder so that the entire machine could be moved ahead by means of an electric hoist working on a cable attached to the timbering ahead. Blowers mounted on the girders were useful in ventilating the heading.

*Steel Sets.*—Where heavy timber lining[4] was insufficient, steel sets with arches and inverts were designed to carry the loads as roughly determined by the failure of dimension timber in the headings. The first, or lighter, steel sets consisted of 24-in. by 80-lb. I-beam posts, three 20-in. by 65.4-lb. I-beam roof segments, and three 18-in. by 54.7-lb. I-beam invert members (Fig. 7) placed on 3-ft. centers so that additional sets could be "jumped in" between if necessary. This had to be done in a few instances. When it became evident that heavier reinforcement was needed to hold the ground until concrete was in place, a "heavy steel set" was designed consisting of two 20-in. by 113-lb. girder beam posts, three 14-in. by 100-lb. H-beam arch members, and three 12-in. by 79-lb. H-beam invert segments. The 10-in. channel collar braces between sets were encased in concrete as soon as they were bolted, in order to prevent twisting as the ground flowed, and reinforced precast foot-blocks were used to prevent undue settlement of the posts (Fig. 7).

Roof arches and 24-in. I-beam wall-plates were first placed, followed by the posts which were set behind the Lewis girder. Between the posts at a distance of about 8 ft. above the floor 12 by 18-in. wooden spreaders were wedged until inverts were fabricated. Some failures occurred in these spreaders and, in a few instances, the ends of the timbers pushed in the flanges of the steel posts more than an inch, causing the web to buckle and necessitating

[4] "Construction Methods on the Moffat Tunnel," by R. H. Keays, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 95.

replacement of the post. In places, the floor squeezed up several inches a day, requiring repeated excavation before being finally filled with concrete.

Costs of timber lining and of steel lining are given in Appendices III and IV.

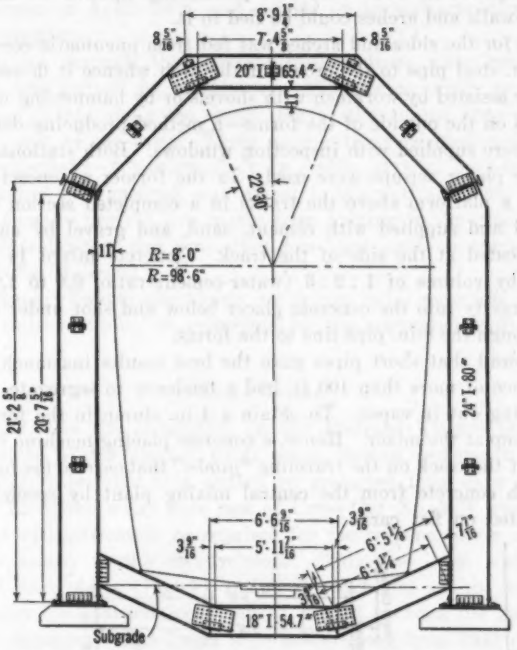

FIG. 7.—STEEL SET FOR TUNNEL LINING—LIGHT TYPE.

*Concrete Lining.*—To minimize this squeezing, which increased with exposure of the soft rock to air and moisture up to a point where arching created a pseudo-equilibrium, concrete was placed in the inverts as soon as possible after the steel. Reinforcement of 30-lb. rails and 1-in. bars was placed between the 5¼-ton steel sets so that the entire lining was consolidated. Folding wooden forms in 4-ft. sections, lined with sheet zinc and suspended by block and tackle from the timber spreaders, were held down by bracing until the concrete set, with the result that none of the concrete was ruptured during the early setting stages. Cement which gave early compressive strength of more than 2 000 lb. per sq. in. in 48 hours and 4 500 lb. in 7 days, was used.

In one of its reports to the Moffat Tunnel Commission, the Board of Consulting Engineers called attention to the tendency of the weak rock, if held securely, to reach a constant distributed bearing, insuring permanent safety. Instrumental observations made on the lining to determine the movement, if any, had shown this to be the case.

Following the lining of the inverts, traveling steel forms, mounted on a timber "jumbo" carriage, were moved along the tracks on the finished invert.

When jacked into position the bottom of these forms was fastened to bolts previously embedded in the upper shoulder of the invert near the keyway joint. In carrying the invert up to this joint, 4 ft. above the center-drain flow line, reinforcing rods were left protruding upward so that the steel for the side-walls and arches could be tied to it.

Material for the sides and arches was fed from pneumatic concrete placers through 8-in. steel pipe to the crown of the arch whence it flowed behind the forms, being assisted by workmen with shovels or by hammering with one-man air hammers on the outside of the forms—a method producing dense concrete. The forms were supplied with inspection windows. Both stationary and moving concrete placer set-ups were used. In the former a concrete mixer was mounted on a platform above the tracks in a completed section of the Railroad Tunnel and supplied with cement, sand, and gravel by endless bucket conveyors located at the side of the track. Concrete mixed 1½ min. in the proportions by volume of 1 : 2 : 3 (water-cement ratio, 0.8 to 1.0) was then poured by gravity into the concrete placer below and shot under 80 to 110-lb. pressure through the 8-in. pipe line to the forms.

It was found that short pipes gave the best results inasmuch as concrete shot a distance of more than 100 ft. had a tendency to segregate, some of the cement blowing out in vapor. To obtain a 4-in. slump in the forms required 6 to 7-in. slump at the mixer. Hence, a concrete placing machine was mounted to one side of the track on the traveling "jumbo" that carried the forms and was supplied with concrete from the central mixing plant by special side-dump bodies mounted on flat cars.

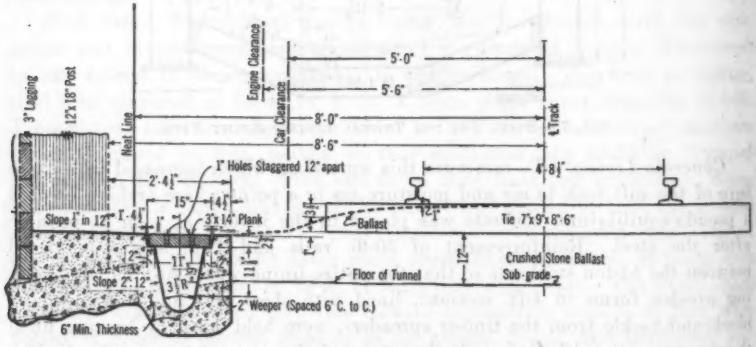

FIG. 8.—DRAINAGE GUTTERS FOR RAILROAD TUNNEL, CROSS-SECTION SHOWING RELATION TO WALL AND TRACK.

In all, 916 lin. ft. of steel lining was buried in concrete and a total of 12 000 yd. of concrete lining was used, including that around the wooden sets. The thickness of the concrete ranged from 1 to 5 ft. Throughout the timbered sections allowance was made for future lining of concrete by setting the posts back. The far-sighted policy of concreting the sections showing greatest need each year, if followed out consistently, will result eventually in a complete permanent lining—a desirable and, in the long run, an economical condition. The cost of concrete lining will be found in Appendix IV.

*Drains.*—Concrete gutters through the timbered sections (Fig. 8) served the dual purpose of protecting the timbers from the deteriorating and undermining effects of water and of anchoring the posts against "kicking in". A capacity of about 3 000 gal. per min. was provided in the gutters, work on which was begun in April, 1926, and carried on by separate crews following the lining operations.

Center drains through the concrete-lined sections were connected with the concrete side gutters by transitions. Tile drains, made to order, were laid with open joints along the south side of the tunnel through the solid rock sections east of the apex. These were entirely covered with ballast.

*Spark Protection.*—A canopy 10 ft. in width, of 1-in. by 4-in. California redwood, tongued and grooved, was nailed to the roof segments through the timbered sections to prevent live sparks from lodging in the cracks and starting fires. This type of fire protection has been used on timbered tunnels along the Moffat Railroad.

*Refuge Bays.*—Twenty-one niches, or refuge bays, were left in the south wall of the railroad tunnel at cross-cuts for the convenience of maintenance crews.

## Water Tunnel

*Steel Plate.*—As the excavation in the Railroad Tunnel progressed the timbering in the Water Tunnel, 62 ft. away, showed movement and distress, making it imperative that this section be protected from cave-ins. Accordingly, 1 485 ft. of the water bore east of Cross-Cut No. 9-W was enlarged to the size that will ultimately be required for the transportation of the Fraser River water supply to the eastern slope. This was lined with corrugated pressed steel liner plates (Fig. 9), inside of which was a 4-in. coat of gunite, with allowance for additional concrete if needed between the gunite and the 10-ft. inside diameter. The liners were cold-pressed from steel plates by dies made to give twelve segments 36 in. long by 16 in. wide by ¼ in. thick and with a 2-in. bolting flange rounded at the corners. This feature, with the corrugations, gave the required strength to units that weighed 50 lb. and could be readily placed by one man. Added strength was obtained when required by splicing ¼-in. segmental stiffener bars between the flanges.

The fact that a full circle of these plates could be bolted and wedged in place to line and grade without disturbing enough of the heavy ground to create a hazard, proved a distinct advantage. Furthermore, excessive excavation was obviated as the steel virtually became reinforcing. Holes were provided at intervals of a few feet so that the packing behind the steel plates could be grouted under pressure. Having thus taken the weight of the ground on this circular steel lining a protection of gunite (1 part cement to 2 or 3 parts sand) was placed to a uniform depth of approximately 4 in.

Loads estimated at 129 000 lb. per lin. ft. were supported by this type of lining without deformation in the steel or cracking in the cement.

*Future Use.*—The Moffat Tunnel Law made it mandatory upon the Commission to provide for transportation of water from the Colorado River Basin on the western slope to the dry eastern slope, the purpose being to increase

the available water supply for the City of Denver. Therefore, plans were made for a parallel bore as close as practical to the Railroad Tunnel that would serve as a service tunnel to speed up construction and later could be enlarged to carry 1 000 cu. ft. per. sec. of water—the capacity required to divert economically 100 000 acre-ft., the mean run-off from the 97 sq. miles of the Fraser River Diversion Project upon which the City of Denver had filed.

To carry water, the tunnel had to be lined throughout the western end from the intake shaft at Station 2696 + 25[5] to the apex at Station 2536 + 81 as well as through approximately 1 500 ft. of scattered seamy sections east of the apex. The remaining 12 200 ft. east of the apex is through solid granite having an average area of 100 sq. ft. (8 by 8 ft. + 50% overbreak) which would carry about 500 sec-ft. until need for the full 1 000-sec-ft. capacity necessitated enlargement or lining, or both.

According to plans contemplated, water collected by a canal system from the Fraser River, Vasquez Creek, St. Louis Creek, Ranch Creek, and tributary streams would reach the 10-ft., circular Water Tunnel through a 209-ft. vertical shaft, 12 ft. in diameter at Cross-Cut No. 3 (2 700 ft. east of West Portal). The water would be forced under pressure (gravity) over the apex, Elevation 9 244, and thence down grade to East Portal, Elevation 9 204, the hydraulic gradient being 0.004. From East Portal a short canal could deliver the water into South Boulder Creek which flows through rocky box canyons to Eldorado Springs on the edge of the plains, 15 miles northwest of Denver, and 500 ft. higher in elevation. This point is also above the head-gates of numerous irrigation ditches serving territory adjacent to the city.

## Ventilation

Air flow tests made at the Moffat Tunnel (Fig. 10) to determine the coefficients of friction of the lining preparatory to deciding upon the specifications for the blowers, furnish valuable data on the relation between flows through tunnels of railroad size and through mine tunnels. The information available on the former is fragmentary, that on the latter, voluminous; so that the rare opportunity offered by the Moffat Tunnel measurements to compare the two simultaneously as the same volume of air was forced through the 8 by 8-ft. and the 16 by 24-ft. bores, will be useful in converting the extensive experimental data on small mine airways to the solution of railway tunnel ventilation problems.

The determination of the power requirements for mechanically ventilating the tunnel, necessitated estimating both the volume of flow desired and the pressure required to circulate this quantity of air through the tunnel. In both these estimates a large number of variables are involved.

*Estimating Volume of Flow.*—Steam operation having been determined upon by the lessee of the tunnel, the primary purpose of ventilation would be to dilute and remove the noxious gases produced by combustion of coal in the engine. The requirements are based on diluting the carbon monoxide of the locomotive exhaust gas to a proportion that would have a negligible effect on man.

[5] "Construction Methods on the Moffat Tunnel," by R. H. Keays, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 66, Fig. 3.

FIG. 9.—WATER TUNNEL, SHOWING WOOD TIMBER LINING BEING REPLACED BY CORRUGATED PRESSED STEEL LINER PLATES.

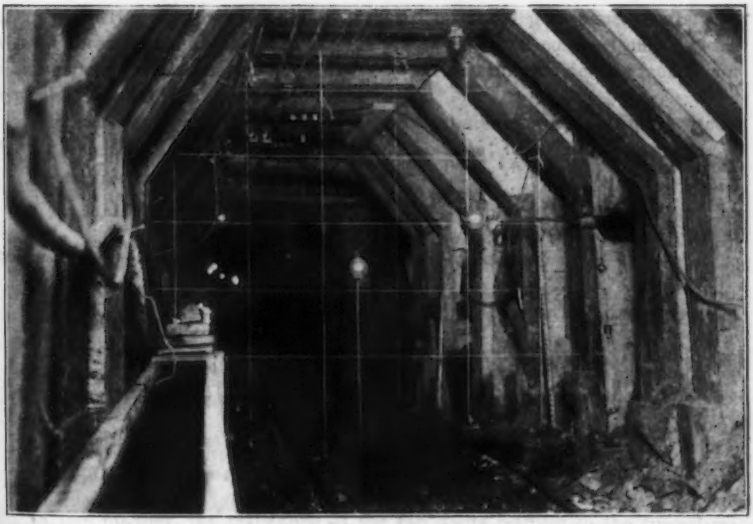

FIG. 10.—AIR-MEASURING STATION IN WATER TUNNEL—DETERMINING MEAN VELOCITY IN CROSS-SECTION.

In arriving at this quantity the following assumptions and calculations have been made:

Maximum train—locomotive and 50 cars: 2 500 tons.
Maximum tractive resistance at 24 lb. per ton on 0.9% grade: 60 000 lb.
Train speed: 10 miles per hour.
Maximum tractive power: 880 000 ft-lb. per sec.
Necessary coal consumption based on test: 0.73 lb. per sec.
Air for combustion at 25 lb. of flue gas per lb. of coal: 18.3 lb. per sec.
Air for dilution, assuming 1% CO in gas (based on tests), diluted to 5 parts per 10 000 (4 parts per 10 000 considered safe limit for 1 hour exposure): 330 lb. per sec.
Quantity required at 0.055 lb. per cu. ft., average weight of air at the tunnel: 360 000 cu. ft. per min.

Actually, this result is considered a maximum in that average maximum values have been assumed throughout.

*Estimating Pressure Requirements.*—The pressure required to cause any particular volume of air to flow through an airway, such as the Moffat Tunnel, depends on the dimensions, velocity of flow, density of air, and the physical characteristics of the airway. The latter must be handled in calculations by the use of empirical numbers which are based on experimental determinations and designated as friction factors or coefficients of friction.

Friction factors for somewhat similar types of mine airways, 40 to 60 sq. ft. in area, were available from experimental work of the U. S. Bureau of Mines, but their application to such large airways (400 sq. ft.) was extremely uncertain as was also the available evidence concerning the effect of area on friction factors, which was based on small pipe experiments. In view of these facts and the lack of preciseness of visual comparison of rough rock surfaces, it was considered necessary to determine friction factors for typical sections of the partly completed tunnel.

These tests indicated that a maximum average value of the friction factor for air weighing 0.055 lb. per cu. ft. would be about 0.000 000 0050.

*Tunnel Resistance.*—Using the formula,

$$R = \frac{K P L Q^2}{A^3} \qquad (1)$$

the resistance of the clear tunnel was calculated as follows:

| | | |
|---|---|---|
| 0.000 000 005 | = | assumed friction factor, $K$. |
| $\times$ 80 | = | average perimeter, $P$, of tunnel sections, in square feet. |
| $\times$ 32 250 | = | length of tunnel, $L$, in feet. |
| $\times$ $(360\,000)^2$ | = | square of estimated quantity of flow, $Q$, in cubic feet per minute. |
| $\div$ $(400)^3$ | = | cube of average area, $A$, in square feet. |
| = 26.16 | = | resistance, $R$, in pounds per square foot. |
| = 5.03 | = | resistance of flow, $\frac{R}{5.2}$, in inches of water. |

In like manner, the resistance of the fan ducts leading to the tunnel was estimated as approximately 0.02 in. of water.

*Resistance of Standing Train.*—No data being available for the resistance caused by moving trains, the resistance of a standing train was first calcu-

lated from experimental data and from rational assumptions. Then the difference in results was used as a criterion in arriving at the resistance of a moving train calculated by the latter method.

With coal mine cars occupying about 20% of the total area, U. S. Bureau of Mines experiments gave an end resistance of 0.45 of the velocity pressure in the clear airway for the first car and 0.15 of the velocity pressure for the side resistance of each additional car when closely coupled. Tests on single cars of different areas indicated that the resistance varied directly as the square of the ratios of car area to airway area. Assuming that the locomotive has an effect equal to 2 cars, that the average train will comprise 50 cars, and that the cars are approximately 9 by 14 ft. in section and thus occupy about 31% of the tunnel area, the total train resistance may be calculated as:

$$\left(\frac{31}{20}\right)^2 \times [0.45 + (52 \times 0.15)] = 19.8 \text{ velocity pressures}$$

At 900 ft. per min., the velocity pressure is 0.037 in. of water for air weighing 0.055 lb. per cu. ft.; therefore, the train resistance is:

$$19.8 \times 0.037 = 0.734 \text{ in. of water.}$$

The resistance of the standing train may also be calculated by considering it made up of two components: The impact against the end, destroying $\frac{125}{400}$ of the velocity pressure, and the actual increase in resistance due to the air moving at higher velocity through the reduced section. The end resistance is then $\frac{125}{400} \times 0.037 = 0.012$ in. Assume a friction factor of 0.000 000 005; and a length of 2 000 ft., with the area reduced to 275 sq. ft., the perimeter increased to 110 ft., and the velocity increased to 1 319 ft. per min. Then the resistance through the reduced section is calculated as 1.318 in. of water. The tunnel resistance without the train is $\frac{2\,000}{32\,250} \times 5.03 = 0.312$ in., therefore the increase will be $1.318 - 0.312 = 1.006$ in. The total train resistance is then $1.006 + 0.012 = 1.018$ in., a result which is approximately 40% higher than that calculated from experimental data.

*Resistance of Train Moving Against the Air Flow.*—Since rational computations approximate experimental results for standing trains, it is felt that a sufficiently accurate calculation of the resistance caused by the train moving against the air flow at 10 miles per hour may be made. In this case the train velocity of 880 ft. per min. is added to the tunnel air velocity of 900 ft. per min., giving a relative velocity of 1 780 ft. per min. for the air impacting on the train, for which the velocity pressure is 0.081 in. of water. The end resistance is then $\frac{125}{400} \times 0.081 = 0.025$ in.

The velocity through the reduced section of 275 sq. ft. is 1 319 ft. per min., while the relative velocity along the train is 880 ft. per min. greater, or 2 199 ft. per min. At 1 319 ft. per min., the resistance of 2 000 ft. of this

reduced section is calculated as 1.32 in., while at 2 199 ft. per min., it is 3.67 in. (See Equation (1).) Considering these values as applying in the ratios of the perimeters involved, the total side resistance would be:

$$\frac{73}{110} \times 1.32 + \frac{37}{110} \times 3.67 = 2.11 \text{ in.}$$

For this section the normal resistance without the train is 0.31 in. and the increase due to the train is 1.80 in. This, added to the end resistance of 0.025, gives a total increase in resistance due to the moving train of 1.83 in. of water. Assuming that the values thus calculated are 40% high, the train resistance is 1.31 in.

*Total Resistance to Flow.*—On the basis of a flow of 360 000 cu. ft. per min., the total resistance has been calculated as follows: 5.03 in. for the tunnel proper; 0.02 in. for the snowshed and fan connection; and 1.31 in. for a train moving 10 miles per hour against the flow, or a total of 6.36 in. of water.

For any other flow the combined resistance may be computed by means of the equation,

$$R = 0.49 \left(\frac{Q}{100\,000}\right)^2$$

in which, $R$ equals resistance, in inches, of water; and $Q$, quantity of air, in cubic feet per minute.

*Natural Draft.*—Immediately after "holing through" the Water Tunnel the flow of air from west to east was measured and found to be 50 000 cu. ft. per min., corroborating the barometric readings made at the two portals.

At these points situated on the opposite sides of a mountain, pressures are rarely the same, due to differences in atmospheric conditions in the columns of air above. Barometric records have been kept at both portals since March, 1925, and these, corrected for difference in elevation, indicate that a strong natural draft from west to east predominates during the winter months, and a variable intermittent draft with frequent reversals, during the remainder of the year.

The average maximum draft west to east may be taken as about 0.3 in. of mercury (4.1 in. of water), a value that is exceeded but four or five times a year and only for relatively short periods. The maximum recorded draft has been 0.7 in. of mercury (9.5 in. of water). The average maximum draft east to west may be taken as about 0.05 in. of mercury (0.7 in. of water), a value that is rarely exceeded and but infrequently attained. The maximum recorded draft has been 0.15 in. of mercury (2.0 in. of water).

The other minor components that might be considered are the difference in weights of the air column inside the tunnel and that at the West Portal through the same elevation; and the effect of wind pressure on the portals. The former amounts to but 0.11 in. for an average difference of 40° in temperature between the inside and the outside of the tunnel, an extreme winter condition of rather short duration. Gales are frequent at both portals during the winter months, blowing against the West Portal and down over the East Portal, the latter probably producing some suction effect.

Thus, natural draft pressures tend to increase the demand upon the ventilating equipment, at least in the winter when strong adverse natural draft has to be contended with in ventilating against the heavily loaded trains moving from west to east up the 0.9 and 0.8% grades west of the apex.

## Air Flow Tests to Determine Friction Factors

Air flow tests were made in March, 1927, shortly after the "holing through" of the Water Tunnel, while the main headings of the Railroad Tunnel were about 1 000 ft. apart and the enlargement operations were about 4 800 ft. apart (Fig. 11). Conditions were not ideal for experimental precision inasmuch as tunneling operations were going on day and night. However, about 20% of the observations were free from interference.

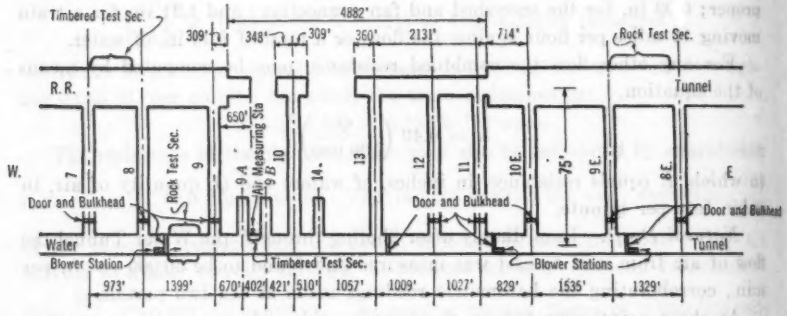

FIG. 11.—AIR FLOW FRICTION TESTS: LAYOUT OF SECTIONS, BLOWERS, AND DOORS.

Velocities were restricted by the high resistance to air flow through the 8 by 8-ft. Water Tunnel and cross-connections between the uncompleted sections of the Railroad Tunnel so that, although this arrangement insured the passage of all air through the gauging station in the Water Tunnel, it kept the maximum velocity through the Railroad Tunnel section down to about 80 ft. per min., equivalent to a flow of 35 000 cu. ft. per min.

*Scope of Test Work.*—Four sections (Fig. 11) were selected for tests: (1) A rock section of the Railroad Tunnel between Cross-Cuts Nos. 8-E and 9-E; (2) a timbered section of the Railroad Tunnel between Cross-Cuts Nos. 8-W and 7-W; (3) a timbered section of the Water Tunnel between Cross-Cuts Nos. 9-A and 9-B; and (4) a rock section of the Water Tunnel between Cross-Cuts Nos. 9-W and 8-W.

*General Statement of Test Results.*—Although individual test results varied widely, especially for short-period tests on the Railroad Tunnel sections, where very low velocities and minute pressure differences were involved, the averages of a large number of test observations seem quite reliable and check almost exactly previous estimates extrapolated from other experimental data. As a result of these tests and their comparison with available data, the friction factors shown in Table 1 were selected as applicable to such large airways.

TABLE 1.—VALUES OF FRICTION FACTOR, $K$, IN THE MOFFAT TUNNEL.

| | FOR AIR WEIGHING: | |
|---|---|---|
| | 0.055 lb. per cu. ft.* | 0.075 lb. per cu. ft. (standard density). |
| Unlined rock | 0.0000000050 | 0.0000000068 |
| Timbered on 4 to 5-ft. centers | 0.0000000045 | 0.0000000061 |
| Timbered on 3-ft. centers | 0.0000000040 | 0.0000000055 |
| Timbered on 2-ft. centers | 0.0000000035 | 0.0000000048 |
| Timbered skin-tight | 0.0000000015 | 0.0000000020 |
| Smooth-lined | 0.0000000010 | 0 0000000014 |

* Estimated average maximum weight of air in Moffat Tunnel.

These values are for use in the standard formula for air flow transformed from Equation (1):

$$R = \frac{K\,S\,V^2}{A \times 5.2} = \frac{K\,S\,Q^2}{A^3 \times 5.2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1a)$$

in which, $K$ is a friction factor, which varies directly as the density of the air, and is given for a standard density of 0.075 lb. per cu. ft., unless otherwise stated; $R$ is pressure, in inches, of water; $S$, rubbing surface, in square feet = perimeter times length; $V$, average velocity, in feet per minute; $Q$, quantity of flow, in cubic feet per minute; and $A$, the average area of cross-section, in square feet.

*Test Methods.*—The determination of friction factors involves the simultaneous measurement of the air flow and the difference in static pressure between the two ends of the section selected for test, together with sufficient observations of barometric pressure and temperatures for determining the weight of the air. From these data and the dimensions of the airway, values of the friction factor, $K$, are computed from Equation (1*a*).

Tests on three of the four sections required the sealing of a door on a main traffic artery, therefore, simultaneous observations were required at three widely separated points, at any one of which test observations might be, and were, interrupted for varying time intervals. Continuous observations were made at all three points for a period of several hours at a time; the results were then compared on a time basis and all those showing interference (about 80%) were discarded before computations were made. The remaining 20% were usually scattered over relatively short periods.

Under the test conditions, air measurement by calibrated anemometers was considered more practical than Pitot tube, or velocity-pressure, methods. Air flow was measured at a timber set in a heavily timbered section of the Water Tunnel just east of Cross-Cut No. 9-A. Preliminary traversing, as shown in Fig. 10, determined the relation of the mean velocity to the velocity at the center of the section and the latter only was measured during pressure-loss tests. A few center velocities, measured simultaneously by anemometer and Pitot tube, were about 2% higher by the latter method, which, considering the difference in areas involved, is ample assurance that the anemometer calibrations used were substantially correct.

Standard U. S. Bureau of Mines static tubes were set up at each end of the test section and pressures from these were communicated to a pressure gauge, near the middle of the section, through 100-ft. lengths of small (⅜-in. inside diameter) pneumatic hose connected by pure gum rubber tubing.

Wahlen differential pressure gauges were used to measure the difference in the pressures communicated through the tubings, to an accuracy of 0.0001 in. of alcohol. Temperatures in the tunnel were almost absolutely constant at any one point, but varied from 58° to 65° Fahr., in the test zone. (Rock temperatures had previously been found to range from 60° near the portals to 68° Fahr., near the center.)

Cross-sectional areas and perimeters were obtained from the graphical records for all sections except the Water Tunnel timbered section which was measured for the test.

## Tunnel Conditions for Tests

*Railroad Tunnel Rock Sections.*—Test sections, 954 and 1 200 ft. long, through blocky granite of average roughness with some gradual area variations and ballasted floor gave an average friction factor value of 0.000 000 0070 for velocities of 57 to 83 ft. per min. (air density, 0.075 lb. per cu. ft.). Compared with previous tests on 60-sq. ft. airways having a friction factor of 0.000 000 0092, an increase of 24% corresponds to the 1:7 increase in area. The low velocities in these large airways do not appear to increase the factor materially.

*Railroad Tunnel Timbered Sections.*—In the sections tested, the timbers were in almost perfect alignment, but the spacings varied irregularly as they do throughout all timbered sections of the tunnel. Expressed in terms of length of section: Three sections, totaling 12%, were timbered skin-tight; six sections, totaling 25%, on 2-ft. centers; six sections, totaling 47%, on 3-ft. centers; and two sections, totaling 16%, on 4-ft. centers. Fig. 12(*a*) shows a typical cross-section.

Four tests on a 890-ft. section, at velocities of 74 to 81 ft. per min., were for 9 to 13 min. duration and were expected to yield very consistent results. The computed results, however, were somewhat erratic and their averages of 0.000 000 0053, although roughly checked by later observations at lower velocities, may be somewhat high.

Three variables are involved in the comparison of this with results secured at high velocities in small timbered airways, namely, the effects of area, of timber spacing, and of low-velocity flow. The tests on the Railroad Tunnel rock section indicate that the latter is negligible; and mine-airways data indicate a factor, $K$, of 0.000 000 0070 with timbers spaced on 5.3-ft. centers, so there is an indicated reduction in $K$ of about 32% for the effects of area and decreased spacing combined.

*Water Tunnel Timbered Section.*—In this section, between Cross-Cuts Nos. 9-A and 9-B, the 12-in. faces of the timbers were in good alignment with but few irregularities and small offsets. The timbers were spaced 18 and 24 in., center to center, in alternate blocks, about one-third the length involved being timbered on 18-in. centers and two-thirds on 24-in. centers.

The floor was of loose muck with the track ties exposed throughout and with the bottom segments exposed for about one-third the length on one side. A water flume, approximately 1.0 by 1.1 ft., occupied part of one side of the section, resting on the floor at the east end, with the space beneath filled with pipes and blocking at the west end. Areas were taken inside the upper braces with no allowance for the spaces between these braces and the caps, since tests have shown that no appreciable flow occurs through such small openings. The shape of the section is shown in Fig. 12(*b*); and the type of surfaces in Fig. 10.

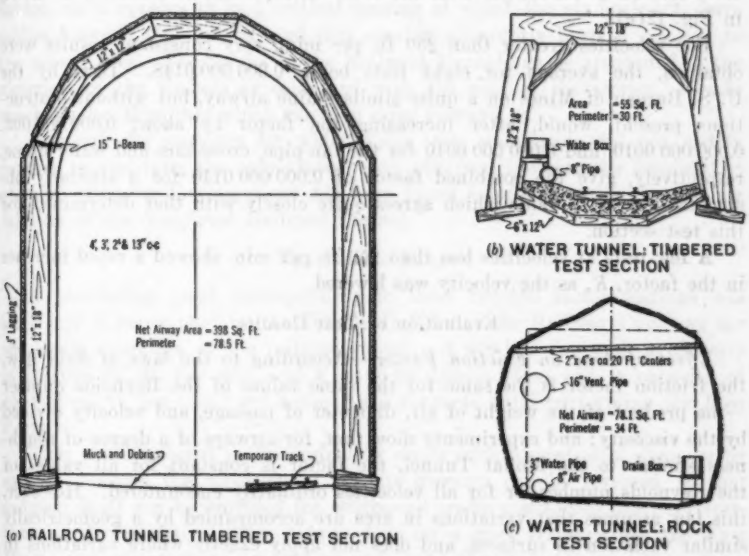

FIG. 12.—AIR FLOW FRICTION TESTS: TYPICAL CROSS-SECTIONS OF TUNNELS USED FOR MEASUREMENTS.

Since all observations were under sight control, 2-min. tests yielded quite consistent results even on different, but overlapping, test sections and in spite of the interference resulting from working on a small main traffic artery. Six tests on six different sections, 310 to 320 ft. in length, gave an average factor, $K$, of 0.000 000 0053 at velocities of 600 to 700 ft. per min. At velocities of 340 to 400 ft. per min., four tests on two sections gave an average factor of 0.000 000 0051.

Later tests at low velocities, with a small amount of timber storage in the test section, gave factors as high as 0.000 000 0073 at a velocity of 171 ft. per min. At 264 ft. per min., the factor was 0.000 000 0057 and, making some allowance for the added obstructions present, it seems that, for this section, a break in the law of flow occurs at a velocity of about 250 ft. per min.

An average value of $K$ of 0.000 000 0052 is indicated for this section for velocities greater than 250 ft. per min. For a quite similar section tim-

bered on 5.3-ft. centers, a factor of 0.000 000 0080 has been determined in mine airways. There is thus an indicated decrease of about 35% as between 5.3 and 1.8-ft. spacing in airways of this size.

*Water Tunnel Rock Section.*—In this section, between Cross-Cuts Nos. 8-W and 9-W, the rock surfaces were more irregular and the area gradations were more abrupt and of greater extent than average conditions in railroad tunnel sections; and not only was the floor much rougher, but the section had a number of obstructions, including a fan pipe, 14 in. in diameter, with flanged joints, a water-flume and blocking, a 3-in. water pipe, an 8-in. air pipe, and 4-in. cross-bars on 20-ft. centers near the roof. A representative section is shown in Fig. 12(*c*).

For velocities greater than 250 ft. per min., very consistent results were obtained, the average for eight tests being 0.000 000 0148. Tests by the U. S. Bureau of Mines on a quite similar mine airway, but without obstructions present, would, after increasing the factor by about 0.000 000 005, 0.000 000 0010, and 0.000 000 0010 for the fan-pipe, cross-bars and water-flume, respectively, give the combined factor of 0.000 000 0140 for a similarly obstructed airway, a value which agrees quite closely with that determined for this test section.

A few tests at velocities less than 250 ft. per min. showed a rapid increase in the factor, $K$, as the velocity was lowered.

## Evaluation of Test Results

*Effect of Area on Friction Factor.*—According to the laws of fluid flow, the friction factor is the same for the same values of the Reynolds number —the product of the weight of air, diameter of passage, and velocity divided by the viscosity; and experiments show that, for airways of a degree of roughness similar to the Moffat Tunnel, the factor is constant for all values of the Reynolds number, or for all velocities ordinarily encountered. However, this law assumes that variations in area are accompanied by a geometrically similar variation in surfaces, and does not apply exactly where variations in area are accompanied by a constant degree of roughness of surfaces.

In estimating factors for Moffat Tunnel sections, approximately 400 sq. ft. in area, from test data on 40 to 60-sq. ft. mine airways of the same absolute degree of roughness, the difference between absolute similarity and geometrical similarity had to be estimated. From rather scanty data the accompanying decrease in factor was estimated at about 25% and the tests on the Railroad Tunnel rock section exactly confirm this result if the assumption is made that the determined factors are not influenced by low-velocity flow. Test conditions did not permit determining the effect of the latter for the large railroad sections, but the results obtained indicate that it was either quite small or negligible. Its effect, if present, would be to increase the factor and to increase the percentage of decrease of factor over that determined. The uncertainty is thus on the safe side.

*Effect of Low-Velocity Flow on Friction Factor.*—Tests on the rock and timbered sections in the Moffat Water Tunnel show a rapidly increasing factor for velocities of less than about 250 ft. per min. Tests on the Railroad

Tunnel sections could only be made for a very limited range of low velocities, but both the determined value of the factors and their close agreement, for the small velocity range of 57 to 83 ft. per min. in the rock section, indicate that, for these large sections, the effect of low-velocity flow on the factor is either quite small or negligible.

*Effect of Timber Spacing on Friction Factor.*—The tests in the timbered sections of the Railroad Tunnel corroborated determinations made in the Water Tunnel which showed that, for the close spacing of 5 ft. or less, the friction factor decreased with the spacing of the sets. Inasmuch as laboratory tests tend to indicate that spacing timbers far apart would decrease the friction factor, there appears to be a critical spacing at which the air begins to form eddies between the timbers, and this spacing apparently bears a relation to the airway area. The results in the Railroad Tunnel can be attributed to the closeness of the timbers as compared with the area of the section, a ratio much smaller than that which exists in mine airways.

Although the purposes for which these tests were made did not justify further expenditure, the comparative data obtained indicate the possibilities of more extensive investigations and were found helpful in estimating the air friction of the completed Railroad Tunnel.

## Ventilating Plant

A ventilating plant corresponding to these friction factor findings was built and is being used by the Denver and Salt Lake Railway Company for the steam operation of the railroad tunnel. A 500-h.p. fan with a capacity of 350 000 cu. ft. per min. and a stand-by 750-h.p. fan, with a capacity of 450 000 cu. ft. per min., are housed in a concrete building forming the East Portal.

They are connected to the tunnel by ducts with hinged steel dampers by means of which the direction of the air currents can be reversed, so that induced draft can be provided for westbound traffic and forced draft for eastbound. A vertically lifting canvas door on a steel frame closes the East Portal during periods of ventilation and is raised automatically when a train approaches. Air-current velocities vary from about 10 to 15 miles per hour.

*Consulting Engineers.*—The Board of Consulting Engineers retained by the Moffat Tunnel Commission was comprised of the late David W. Brunton, M. A. I. M. M. E., *Chairman*, J. Waldo Smith, Hon. M. Am. Soc. C. E., and L. D. Blauvelt and J. Vipond Davies, Members, Am. Soc. C. E.

This Board rendered valuable service during the construction of the project. When unexpected difficulties demanded utmost co-operation and resourcefulness it suggested, among other expedients, the use of the steel wall-plates. Its recommendation that the Water Tunnel be lined west of the apex is being gradually accomplished.

## Economic Value of the Tunnel

The project involved $15 470 000 outstanding bonds. The first issue amounted to $6 720 000 at 5½%; the second, $2 500 000 at 5¼%; the third, $3 500 000 at 5¼%; and the fourth, $2 750 000 at 5 per cent. Real estate of

the Moffat Tunnel Improvement District, of which Denver represents 89%, is security for these bonds, and a total cost, including earnings of camps and interest during construction, of $18 000 000, in round figures, must be of pronounced economic value to justify this investment.

The purpose of the tunnel was threefold:

1.—To eliminate about 30 miles of 4% grade over Rollins Pass, lowering the maximum altitude from 11 660 ft. to 9 240 ft., which is below the snow areas, reducing the ruling grade to 2.0% and the maximum curvature to 12°, and eliminating 10 800° of curvature; all of which was important to the life of the Denver and Salt Lake Railroad.

2.—To place Denver on a through transcontinental rail route, saving 173 miles between Denver and Salt Lake City, by either building the 41-mile Dotsero Cut-Off, connecting the Denver and Salt Lake Railroad with the Denver and Rio Grande Western Railroad, or extending the Denver and Salt Lake Railroad from its present terminus, Craig, to Salt Lake City, Utah; and at the same time to assure adequate transportation facilities for a vast area in Northwestern Colorado rich in timber, coal, oil, oil shale, live stock, and agricultural and mining resources.

3.—To provide a conduit for the transportation of water from the Upper Colorado River on the western slope to the dry eastern slope around Denver, for municipal and agricultural purposes.

Progress toward accomplishing these results may be noted:

(1) The physical railroad improvement has been accomplished.

(2) Negotiations for the construction and use of the proposed Dotsero Cut-Off are under way with both the Denver and Rio Grande Western and Denver and Salt Lake Railroads as probable users. Applications are before the Interstate Commerce Commission.

(3) The City of Denver has entered into a contract for the use of the Water Tunnel as a carrier for its Fraser River water. It is proposed under this contract that the City pay $1.00 per year rental, maintain the water bore, and eventually assume the cost of actual lining as part of its water-supply development program.

The indirect returns from these proposed uses of the tunnel should be increasingly great, obscuring the difficulties of construction and constituting another chapter in the story of the Moffat Tunnel.

# APPENDIX I

## MOFFAT TUNNEL—COST DATA

### Itemized Cost of Rock Excavation in 8 by 8-Foot Tunnel and Headings.

(Average overbreak beyond 64 sq. ft. = 50%; cost based on yardage within 8 by 8-ft. pay line = 171 580 cu. yd.; these costs do not include plant cost, camp, or interest charges, or overhead beyond the superintendent.)

| Item No. | Labor. | Cost per cubic yard. | Item No. | Supplies. | Cost per cubic yard. |

## MOFFAT TUNNEL—COST DATA

### Cost of Timber Lining

(In dollars per 1 000 ft. B. M. in place; for 1 000 ft. B. M. per linear foot of tunnel, see attached typical timbering drawings; standard 5-segment, 12 by 12-in. set = 1 050 ft. B. M.; spark protection = 10-ft. wide canopy of 1 by 6-in. California Redwood nailed to permanent segmental arch timbers.)

| Item. | Labor. | Material. | Total. |
|---|---|---|---|
| Oregon fir in railroad tunnel | 57·11 | 52.67 | 109.78 |
| Native Lodgepole pine in railroad tunnel | 121.84 | 56.56 | 178.40 |
| Timber in water tunnel | 88.53 | 27.79 | 116.32 |
| Cost per linear foot of tunnel | 1.01 | 0.85 | 1.86 |

# APPENDIX IV

## MOFFAT TUNNEL—COST DATA

### Average Cost of Steel Lining in 16 by 24-Foot Railroad Tunnel.

| Item. | Labor. | Material. | Total. |
|---|---|---|---|
| Arch | $ 99.71 | $252.88 | $352.59 |
| Pair of posts | 151.19 | 353·15 | 504.34 |
| Invert set | 31·74 | 84·17 | 115·91 |
| Complete set | $282.64 | $690·20 | $972·84 |
| Cost per linear foot of tunnel sets on about 3-ft. centers | $112.34 | $234.74 | $347.08 |

Cost per linear foot of concrete lining (inverts, side-walls and arches), 8·5 cu. yd. at $31.74 = $270.00

## DISCUSSION

J. VIPOND DAVIES,[6] M. AM. SOC. C. E. (by letter).—In order to give a complete story of the work, this valuable paper must be read in connection with the previous one by R. H. Keays, M. Am. Soc. C. E.[1] Certain aspects which had influence and bearing on the final result, are considered in the following discussion.

In 1913, the Tunnel Commission of the City and County of Denver, by its Board of Engineers, Messrs. Brunton, Davies, and Finch, after considering carefully a geological report prepared for the Commission, reported on the project, recommending the present general location and profile of the tunnel. Further, under pre-war conditions, estimates of the probable cost of the tunnel construction were prepared. At that time the question of water supply was not looked upon as important, but to meet the requirements of the law it was contemplated that pipe conduits might be laid in the floor of the tunnel itself. It was also contemplated that the railroad tunnel would be equipped and operated by electric power. The geological report indicated no likelihood of encountering anything but sound hard rock, although it might be of varying texture and character.

In the preparation of the Moffat Tunnel Law, no reconsideration was given to the excessive advances in cost under post-war conditions, and only an arbitrary addition was made, as stated in the New Act, in the sum of $2 300 000 over that provided in the earlier law, which had been declared by the Courts of Colorado to be unconstitutional.

The Engineering Board and Staff consequently came into the problem of construction of a new project with hands already tied, on a definite location and elevation, with an estimated cost declared in the text of the law, and with a real problem for water supply to be included. The Commission had power to equip and electrify the tunnel and approaches for operation. In earlier years this electrification had been desired and planned by the Railroad Company, and, it was anticipated, would be installed in the completed tunnel.

Previous to the preparation of plans for the tunnel, as now constructed, the Board visited the site with the State Geologist, who indicated that the glacial valley erosion, on the west slope, might be deep, so that if a change were made in the location by a few hundred feet in a southerly direction, it would ensure the entire western half of the tunnel being in solid rock throughout. As is now known, that view was only partly correct, for, although the rock existed continuously, its physical structure was most deficient. The doubt on the part of the Geologist, was that the glacial valley would be so deep as to intersect the tunnel section in the branch of Buck Creek nearest the Western Portal. There was no doubt expressed as to the quality of bedrock where found.

With rock of more or less uniform character there appeared no reason why progress in driving should not have been equal from both ends; consequently, the grade of 0.8% originally contemplated was increased to 0.9%, with the

[6] Cons. Engr.; Pres., Jacobs & Davies, Inc., New York, N. Y.

apex of the eastern and western gradients as nearly as practicable at the middle point of the tunnel. This increased grade would be no detriment if the railroad were to be operated with electric power, particularly as the approach grades at both ends are 2% up to the tunnel portals. The eastern gradient of 0.3% was maintained for proper drainage. The work of construction was in active progress with those established gradients, when the Railroad Company determined that it would not electrify for operation, but would use steam power, for which it considered the 0.8% gradient to be vital, and artificial ventilation to be an absolute essential.

In view of the fact that the rock generally from the Eastern Portal to the ridge of the Rocky Mountains was hard and practically dry, it was not thought that the driving of the eastern end over the apex for a longer distance would be of material consequence. From this change arose one of the serious difficulties which developed later and has been recorded.

Mr. Betts refers to the absence of diamond drill borings. It is open to question whether such borings, if made, would have altered the situation. It appears certain that the pre-conception of the Geologist as to the depth of the glacial valleys on the western slope was probably under-estimated. An attempt was made, before finally determining the axis location, to dig pits from the surface in order to locate the rock floor below the west branch of Buck Creek, only to find glacial moraine of boulders and gravel, bearing heavy water. The rock in the tunnel on the western side of the Rockies, to outward observance, is sound native material, but has been rotted, probably by water infiltration on imperfectly fused material. It seriously lacks supporting strength. Even in the small section of the Water Tunnel, it would not carry its own loads without close timber support.

Further, the moraines are a vast reservoir of water from melted snow, as that is practically the only source of water to creeks or on the soil, from higher elevations. As Mr. Betts states, while only a few thousand feet of the tunnel was ever anticipated to require artificial support, the final result proved that every bit of the western half needed both temporary and permanent support. Further, the heavy water encountered in the tunnel driven from the East Portal, was tapped practically under the summit of the Continental Divide. This clearly shows that the fissures in the rock through which the water flowed came from the great Ranch Creek Moraine on the west slope of the mountains.

As long as the railroad was expected to be electrified, there was little concern as to the ventilation of the 6¼ miles of tunnel through the mountain, particularly as the usually existing higher barometric pressure at the western end, added to the difference in actual elevation of the portals, made it certain that there would be adequate current of air to provide purity for passengers and workmen, as well as for cattle, which constitute an important element in the traffic eastward. When, however, it was finally determined that the railroad would be operated by steam power, the problem of ventilation became of vital importance, necessitating determination of those factors relative to which little or no authoritative information was available, particularly as to

the frictional resistance to the movement of air in such a tunnel. The Engineering Profession is deeply indebted for these investigations to the U. S. Bureau of Mines, its engineers, and to Mr. Betts. The present method of operation and ventilation can be considered efficient only until the time is reached when traffic over this route increases so as to require electrification.

The general administration of the work was excellent throughout, both in respect to the Commission and its officers, as well as on the part of the Contractors and their staff. The high elevation and remoteness of the camps were sources of anxiety from the first. The original specifications, prepared in the hope of obtaining straight unit price bids, were greatly elaborated so as to obligate any contractor to install and maintain the most complete possible equipment, sanitary facilities, and general camp hygiene. Notwithstanding the fact that the provisions of the contract and administration of the work were completely changed, those provisions as outlined were carried out to the fullest limit, to the great advantage of the work.

R. H. KEAYS,[7] M. AM. SOC. C. E. (by letter).—This valuable contribution supplements the paper previously submitted by the writer,[1] especially relating to events after 1925. The very valuable description of the ventilation experiments and the ventilation plant move one to attempt to supplement this feature and make a few general remarks on the ventilation of long railroad tunnels.

Besides the system described by the author, which is dependent upon direct air pressure or suction, there is the well-known Sacchardo System of induced ventilation. In this system the mass of air in the tunnel is pushed forward by the pressure caused by numerous jets of high-velocity air, introduced at one of the portals of the tunnel. These air jets are arranged in an annular ring and point into the tunnel parallel to the walls.

The Sacchardo System requires a ventilating fan to work against a much higher pressure than the direct displacement system. Because there is a rather definite and low limit to the pressure to be developed by a fan, and because the longer tunnels naturally require greater pressures, it is very difficult to apply the system to the longest tunnels.

An important objection to its application is that in the Sacchardo System the current of air is not reversible unless one has a plant at each end. The great advantage of the system, however, is that both portals of the tunnel are open at all times, so that the ventilation system will always function. With the direct-pressure system, there can be no ventilation when the closing of the curtain door is obstructed by a passing or standing train.

In any system of ventilation the question also arises as to whether to blow with or against the movement of the train. In the system as described by Mr. Betts, the ventilation is against the train. Ventilating with the movement of the train, however, is somewhat safer in that the smoke from the locomotive travels ahead rather than back among the passengers and crew. To blow with the movement of the train, however, requires much greater volume and velocity of air, unless the speed of the train is kept very slow.

[7] Chf. Engr., Ulen & Co., Athens, Greece.

In the case of the Moffat Tunnel, it is impracticable to rely on the Sacchardo System installed at either end. At the east end, the air pressures would have to be made high enough to overcome the large and almost continuous difference in the barometric pressure of the atmosphere between the two portals, while, if installed at the West Portal, the blowing would have to be in the same direction as the heavy traffic. A plant installed at the West Portal would also cost much more than one at the East Portal because the electric power, presumably used for operation, comes from a generating plant on Boulder Creek, which is some distance from the East Portal. A power line over the range would be difficult to maintain and a line through the tunnel itself would be very expensive.

The Sacchardo System, as the writer understands it, was first applied on one of the Apennine Tunnels, in Italy, and was so successful that later it was used on all other mechanically ventilated tunnels in Europe, with the single exception of the Simplon Tunnel. In each case the blowing was against the heavy traffic. In the case of the Simplon Tunnel, which is single track and more than 12 miles long, it can be imagined that some very high pressures would have been necessary with the Sacchardo System to induce sufficient draft. The only recourse, therefore, was the direct-pressure system.

The writer has had the pleasure of passing through most of the long tunnels of Europe and wishes to note here that there is apparently no longer any ventilation problem because all the railways have been electrified. Trains pass through at high speed, and one is hardly aware of the existence of the tunnel.

A. A. EREMIN,[8] ASSOC. M. AM. SOC. C. E. (by letter).—This paper, together with that entitled "Construction Methods of the Moffat Tunnel", by R. H. Keays, M. Am. Soc. C. E.,[1] is of much value to the profession; it describes many interesting engineering and economical features of tunneling. Moreover, in his reference to the late David H. Moffat, the author calls attention to the fine public spirit of one engineer who worked with untiring activity for the welfare of a city.

The author has stated that observations on the lining of the tunnel have proved the statement made by the Board of Consulting Engineers that if weak rock is held securely it has a tendency to reach a constant distributed bearing, thus insuring permanent safety. This statement is in agreement with the theory of pressure on deeply overlaid tunnels as developed by Kommerell.[9]

When a tunnel is excavated in a soil of uniform cohesion an arch effect occurs over the bore, and the pressure on the lining will be expressed by the weight of the area of the parabola, $A\,B\,C$, in Fig. 13 (*a*). If a side pressure occurs, the loading diagram will be expressed by the shaded area in Fig. 13 (*b*). The curve, $A'\,C'\,B'$, is a parabola or, for practical purposes, it may be considered as an ellipse. Since the height, $H$, in Fig. 13, is a function of the cohesive properties of the ground, a comparatively uniform bearing pressure will occur in the arch roof of the tunnel unless it is complicated by some physical or chemical action in the soil.

[8] Asst. Designing Engr., Bridge Dept., State Highway Comm., Sacramento, Calif.

[9] Kommerell, "Statische Berechnung von Tunnelmauerwerk"; see, also "Tunneling," by Eugene Lauchli, 1915, p. 104.

In discussing timber lining, the author refers to the previous statement[10] by Mr. Keays that "the decision to try to hold this heavy ground permanently with timber only was a bold one."

From Fig. 13, it is evident that the pressure on the tunnel lining varies with the size of the tunnel and the arching effect of the ground and that it does not depend on the depth of the overlying mass.

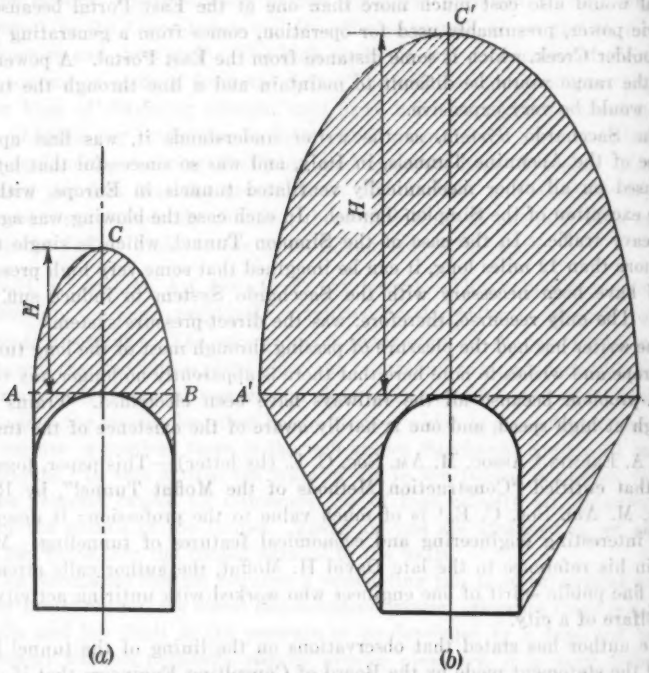

FIG. 13.—DIAGRAMS SHOWING EARTH PRESSURE ON TUNNEL LININGS.

The most common cause of failure in the timber of a segmental arch rib is due to shear at the joints.[11] Many factors can be blamed for this local development of shear, namely, poor workmanship, local and uneven distribution of swelling in the ground, soft material, unsymmetrical stratification of the ground in relation to the center line of the tunnel, and an insufficient number of segments used in the arch ring.

In actual practice it is very seldom that the soil penetrated by a tunnel is of uniform formation. Usually, it is cut by seams and fissures and shattered by faults. A geological survey is expensive and, therefore, in order to have a greater factor of safety, a structural material with better resistance to shear and flexural stresses than timber is usually selected for the lining of deep tunnels. A serious disadvantage of timber lining is the difficulty of preserving

[10] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 95.
[11] *Engineering News-Record*, December, 1927, p. 1039.

it from decay. High temperature, moisture, and chemicals dissolved in the ground are very injurious.

Useful information concerning soil pressure may be obtained from an observation of timber lining left for some time to support the ground before enclosing it in concrete for the permanent lining.

Information on tunneling is scarce in technical literature. Therefore, this paper is especially important to the Engineering Profession.

CLIFFORD ALLEN BETTS, M. AM. SOC. C. E. (by letter).—The valuable discussions have brought out some important points. Mr. Davies' reference to the limitations imposed on the Engineering Staff by legislative action and, later, by legal contracts, illustrates the interdependence of economic feasibility, sound engineering construction, and adequate provisions for repayment of cost, all of which are essential to the ultimate success of projects in general and of this one in particular.

The merits of electrification, especially where a heavy volume of traffic is involved, are indicated in Mr. Keays' outline of European practice, which he has had an unusual opportunity to study. Electrification of the Moffat Tunnel had been taken for granted up to the time the lessee exercised the option of steam operation. The capacity of the tunnel has been estimated at forty trains daily. This use is contingent upon utilization of the Dotsero Cut-Off for which the way was cleared in 1930 by the United States Court decisions validating the lease with the Denver and Salt Lake Railroad Company and by the Interstate Commerce Commission's approval of the acquisition of the Denver and Salt Lake Railway by the Denver and Rio Grande Western Railroad Company.

The effect of steam operation on this partly timbered, 6-mile tunnel will be watched with interest in order to determine whether the chemical action of hot flue gases and the subsequent forced ventilation drafts accelerate deterioration. In this connection, the statement by Mr. Eremin that "a serious disadvantage of timber lining is the difficulty of preserving it from decay", is apropos and explains the recommendation that a concrete-lining program be carried out as maintenance replacements of timber become necessary. This would permit deriving the maximum use of the investment in treated timber lining, would defer large interest charges on concrete, and would provide an opportunity to study the unusually severe ground pressures prior to concreting the remainder of the bore.

There is a wide range in physical and chemical properties of ground. The Moffat Tunnel contained numerous formations from blocky, solid rock unaffected by weathering to a squeezing and swelling fault zone material that produced upward pressures in the tunnel floor, as well as top and side pressures. This type of ground (which might be added to the two illustrated by Mr. Eremin in Fig. 13) is difficult to hold because the flowing pressures find the weakness of the lining whether it be by shear at the joints or by bending of segmental arch ribs or posts. In shortening timber arch members to approach a circle the stability of the arch is endangered, but if steel members are used, the circular arch provides most effective resistance to such pressures. This is being borne out in the Water-Tunnel lining.

An excellent opportunity to substantiate Mr. Eremin's statement that "pressure on the tunnel lining varies with the size of the tunnel and the arching effect of the ground", occurs in two tunnels with which the writer is connected. A 3.55-mile water tunnel, of the horseshoe type, 16 ft. 7 in. in diameter, is being driven at approximately right angles to a 4.15-mile tunnel, 9 ft. 3 in. in diameter, with only 300 ft. separating the inlet portal of one from the outlet of the other. Where similar lava and tuff are encountered in each, the smaller tunnel stands without support, while the larger bore requires 10 by 10-in. fir timbers on 5-ft. centers to hold the ground until the concrete is placed. The difference in pressure between the two tunnels is very noticeable. Advantage can be taken of this fact in determining the economic balance between cost of lining and the excavation costs in designing tunnel sizes.

Recent developments on the Colorado River emphasize the strategic location of the Moffat Water Tunnel for diversion of a water supply for Denver, Colo., from the head-waters of that stream. Due to the rapidly increasing value of water in the arid West and the natural limitations of the watersheds available for serving Denver by gravity, this Water Tunnel has great potential value.

# RAINFALL CHARACTERISTICS AND THEIR RELATION TO SOILS AND RUN-OFF[1]

By C. S. Jarvis,[2] M. Am. Soc. C. E.

With Discussion by Messrs. George S. Bliss, Brehon B. Somervell, Jesse W. Shuman, Clinton L. Bogert, R. W. Powell, Glen N. Cox, C. R. Pettis, George C. Danforth, and C. S. Jarvis

## Synopsis

Investigators of projects involving either flood control or the development of water resources frankly recognize the need for additional records of primary rainfall observations, and also for a fuller use of those already collected and published.

Ever-increasing and voluminous reports appear from time to time dealing with meteorology, hydrography, and soil moisture; with the development, surveys, and classification of soils; with erosion and its control; with the varying yields of water-sheds; and with the volume of floods, and their probable frequency of occurrence. All these data must be rigorously condensed in some manner before they can be used to the best advantage.

The purpose of this paper is to present summarized information regarding precipitation and its occurrence in various countries and latitudes; its relation to soils and run-off; the vegetative, topographic, and physiographic features of the water-sheds; and the resultant influence on designs of drainage structures and channels.

## Form of Data

Precipitation records for the principal stations throughout the world have been assembled in compact form in Table 1 (Appendix I), with both the

[1] Revision and extension of a thesis submitted for the degree of Ph. D., at American University, Washington, D. C., 1927; written with co-operation of U. S. Bureau of Public Roads. Published in January, 1930, *Proceedings*.

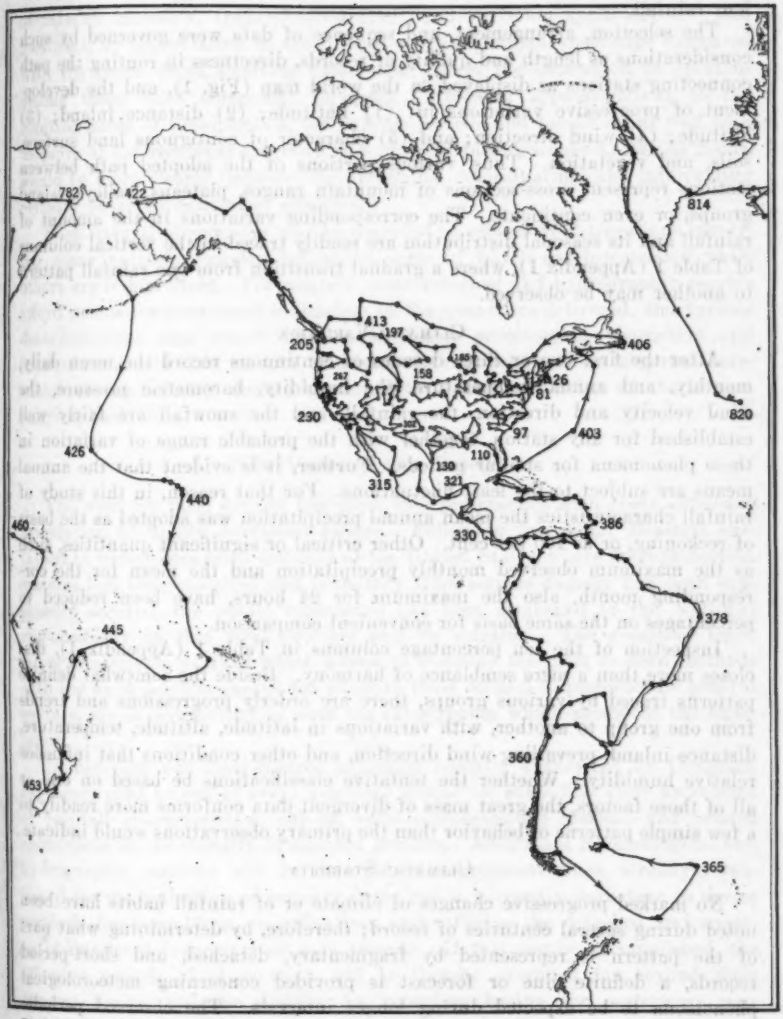

FIG. 1.—KEY MAP OF WORLD SHOWING SEQUENCE OF STATION NUMBERS FOR PRECIPITATION RECORDS—WESTERN HEMISPHERE AND PACIFIC OCEAN.

average habits and the observed range of variation clearly represented. The references from which these data were obtained are given in Appendix II. Wherever snow or hail is included in the observations, it is reduced to equivalent rainfall.

The selection, arrangement, and sequence of data were governed by such considerations as length and quality of records, directness in routing the path connecting stations as displayed on the world map (Fig. 1), and the development of progressive variations in: (1) Latitude; (2) distance inland; (3) altitude; (4) wind direction; and (5) character of contiguous land surface, soils, and vegetation. Thus, various portions of the adopted path between stations represent cross-sections of mountain ranges, plateaus, valleys, island groups, or even continents. The corresponding variations in the amount of rainfall and its seasonal distribution are readily traced in the vertical columns of Table 1 (Appendix I), where a gradual transition from one rainfall pattern to another may be observed.

## Climatic Variation

After the first two or three decades of continuous record the mean daily, monthly, and annual temperature, the humidity, barometric pressure, the wind velocity and direction, the rainfall, and the snowfall are fairly well established for any station, together with the probable range of variation in these phenomena for similar periods. Further, it is evident that the annual means are subject to the least fluctuations. For that reason, in this study of rainfall characteristics the mean annual precipitation was adopted as the basis of reckoning, or as 100 per cent. Other critical or significant quantities, such as the maximum observed monthly precipitation and the mean for the corresponding month, also the maximum for 24 hours, have been reduced to percentages on the same basis for convenient comparison.

Inspection of the ten percentage columns in Table 1 (Appendix I), discloses more than a mere semblance of harmony. Beside the somewhat definite patterns traced by various groups, there are orderly progressions and trends from one group to another, with variations in latitude, altitude, temperature, distance inland, prevailing wind direction, and other conditions that influence relative humidity. Whether the tentative classifications be based on one or all of those factors, the great mass of divergent data conforms more readily to a few simple patterns of behavior than the primary observations would indicate.

## Climatic Stability

No marked progressive changes of climate or of rainfall habits have been noted during several centuries of record; therefore, by determining what part of the pattern is represented by fragmentary, detached, and short-period records, a definite clue or forecast is provided concerning meteorological phenomena to be expected during longer intervals. The observed periodic changes usually complete their fluctuations within forty years, or thereabouts, according to authoritative opinion among meteorologists; but some stations require only twenty, whereas others need more than seventy, years for that purpose.

## Determinate Limits

While it has long been recognized that there may be somewhat definite limits of rainfall intensity, frequency, duration, and variation applicable to given localities, an appreciation of the limited scope of human knowledge compared with the broad fields awaiting exploration deters the expression of opinions among those most competent to speak. Probably approximations to the limiting rates of precipitation for various periods and localities, as well as a measure of the resultant excessive run-off or surface drainage known as floods, would be more clearly indicated by arranging, co-ordinating, and interpreting primary observed data more effectively.

Such natural phenomena may be regarded as successive integrations involving many variable complex influences, some of which are interrelated while others are independent. Fortunately, meteorological and hydrographic records afford means for occasional evaluation of the quantities delivered, and further determinations may result from such simple processes as proportion and interpolation. In this manner solutions of practical problems reported herewith were undertaken during the assembling and tabulation of the accompanying basic data.

## New Views of Old Problems

The need for flood control has come into prominence with every extensive inundation of highly developed valleys. Following the recent disasters sustained in widely separated districts of the United States, where flood-protection systems had been installed and immunity from serious damage had been supposedly secured, the public conscience has been awakened to the National responsibility in this vital problem and its solution. The resulting legislative enactments of 1928 which aimed to combine the most modern methods with the most positive means for effective flood control to promote the general welfare, are as noteworthy as were the catastrophes which prompted the legislation.

In carrying out flood-control programs recently authorized by Congress, engineers need to utilize every available means for extending their knowledge of rainfall characteristics, run-off rates corresponding thereto, and related phenomena in the vicinity of selected projects. Additional meteorological and hydrographic stations will be required to supplement those already established for the collection of primary data; but it is equally important to devise methods for assembling, co-ordinating, and utilizing the detached and apparently unrelated fragments of such records. If this can be accomplished, the effective periods of observation will be thereby extended far beyond their present limits, and the designs for retarding basins and waterways may embody proper consideration for both economy and safety.

If the source of supply and also the most frequented routing or paths of storms are known for a given area, and some fragmentary data are

available to disclose any part of the rainfall pattern, then the information in Table 1 (Appendix I), should furnish something of an index for completing the other parts of the record by comparison with available data pertaining to stations similarly situated and drawing on the same supply. Apparently, the characteristic percentage relations hold fairly consistently in such cases, regardless of the variation in rainfall traceable to the physical configuration of the land surface, except in arid regions.

Outstanding examples to illustrate that principle are furnished by the percentage columns for New England stations, others in Germany, and such adjacent but quantitatively varying stations, as Oviedo and Bilboa, in Spain (Nos. 683 and 684); Ben Nevis and Fort William, in Scotland, if adjusted to the same period of record (Nos. 717 and 718); and Tiflis and Lenkoran, in Trans-Caucasia (Nos. 762 and 763).

Both length and reliability of records, as well as completeness of detailed information and its representative character for either groups, areas, or the range of their habits, were sought among stations included in Table 1 (Appendix I).

### Interrelation Between Meteorological and Hydrological Phenomena

An adequate understanding of the cause-and-effect relation between rainfall and run-off must likewise include the range of conditions which may influence the rate, sequence, and continuity of the various natural processes involved in the rain-producing cycle. Such conditions may include solar radiation, atmospheric circulation and convection, evaporation, expansion, cooling, condensation, deposition, percolation, stream flow, and the accretions or losses sustained en route.

Often arrested or interrupted processes are observed in the meteorological cycle, such as extended cloudy periods without rainfall, or the more advanced stage in which a downpour actually begins in the upper atmosphere, but is dissipated in the lower strata before reaching the earth's surface, producing the familiar cloud-drapery appearance above desert regions. Likewise, the detention and regulation effected by the soil and vegetation during moderate showers may interrupt the run-off and reduce it to a negligible quantity. Under ideal conditions practically all the rainfall percolates into the voids of the soil, and emerges therefrom at a gradually decreasing rate until new accessions of moisture are available.

Maximum river stages usually result from the coincidence of either intense rates or prolonged periods of precipitation or of thawing, together with low absorptive, interceptive, and retentive powers of the soil and its cover.

### Water-Shed Characteristics

Types, structure, color, and stages of development of soils and the varieties of plant growth sustained thereon, provide a supplemental record awaiting

interpretation as to rainfall and run-off habits, whether they be irregular and violent or steady, gentle, and dependable. Thus, the 143 sq. miles of drainage area along Queen Creek, in Central Arizona, with an average annual precipitation of 15 in., produced a high flood volume of 9 000 cu. ft. per sec., but maintained an average flow of only 15 cu. ft. per sec. throughout the year, representing a yield of 10% from the water-shed; by comparison, an equal area along Cedar Creek, in Northwestern Washington, with an average annual rainfall of 120 in., attained an observed maximum flow of 3 600 sec-ft., a minimum of 294 cu. ft. per sec., and an average discharge of 1 089 cu. ft. per sec., a yield representing nearly 90% of the total observed precipitation.

Both the soils and the vegetation that abound in those two regions emphasize the contrast between the steady, gentle, dependable rainfall of the Pacific Northwest as opposed to the sudden, irregular, brief, torrential downpours that are so characteristic of desert regions. The soft, mossy banks, the tender foliage, and the sodded slopes are identified with precipitation which develops almost imperceptibly from fog or mist; while the spike foliage, thorny stems, and other resistant equipment of desert growth reflect the struggle for existence.

There are known physical limitations as to the moisture capacity of the atmosphere for given temperatures and pressures, and there may be just as definite limits for barometric pressure gradients and the wind velocities induced thereby; likewise for storm movements and areas affected, rates of evaporation and condensation, heating and cooling, also freezing and thawing, for designated seasons and localities.

### Limitations Governing Atmospheric Moisture

The high transparency of clear, dry air allows the transmission of nearly 90% of the normal solar radiation under most favorable conditions. The losses due to reflection, absorption, and conduction are all increased by the presence of foreign substances, including water vapor, so that the radiant energy reaching the earth is reduced accordingly. After condensation has proceeded far enough to form dense cloud masses, practically the entire solar radiation is intercepted.

An average measure of the sun's radiant energy that reaches the outer atmosphere may be expressed as 2 calories per sq. cm. per min., or $\frac{1}{3}$ h.p. per sq. ft. of normal surface continuously during sunlight hours. If transmitted to the earth without loss, this energy would be capable of evaporating a 1-in. depth of water at 72° Fahr. during 12 hours near the equator, or from two-thirds to one-half this quantity in mid-latitudes. However, the actual toll of energy taken by the atmosphere during average fair weather conditions is nearly 50%; and during cloudy periods it becomes 90%, or more.

Taking into account the varying opportunities for evaporation as determined by the prevailing temperatures, the inclination of the sun's rays, the

soil moisture content, the degree of cloudiness, the vegetation and foliage, the wind movements, and the atmospheric humidity, it is estimated that, on an average, the equivalent of 0.1-in. depth of water over the entire surface of the globe becomes vapor each day. The upper limit of evaporation rates attainable from free water surfaces may equal 1 in. daily. Illustrative of local variations, the recorded annual evaporation from a tank on the ground at Indio, in the Imperial Valley, California, was 119 in.; from a tank 10 ft. above the ground, 200 in.; from the saline waters of the Salton Sea itself, 72 in.; from a tank 2 ft. above the surface of Salton Sea, 106 in.; from a tank 40 ft. above the water, 140 in.; from a tank on the desert, 165 in.; and from one that was elevated 40 ft. above the desert, 195 in.

Representative evaporation rates for several important stations are shown in Table 2. Main references to this table may be found in Appendix III.

## Evaporation Compared with Precipitation

Comparison of the corresponding columns in Table 1 (Appendix I) and Table 2 indicates the normal relationship between evaporation and precipitation phenomena, especially as regards maximum observed rates. The evaporation process is more or less continuous, while rainfall is usually periodic; the one is governed by atmospheric circulation and temperatures affecting surfaces of known or readily ascertainable areas, while the other depends on condensation of cloud volumes at considerable heights, in air strata which may be moving in different or opposite directions from those below.

*These average values were computed for normal pressure at sea level and were based mainly on Smithsonian Physical Tables. The last column quantities represent moisture content subject to precipitation.

Except for those few stations of extremely high or low rainfall, there are corresponding values to be found for both monthly and yearly means and maxima; but the range of variation from normal is not so wide for evaporation, representing receipts of atmospheric moisture, as for precipitation, representing expenditures. The brief mid-day showers of the tropics exemplify the expenditure of an entire day's accumulation of atmospheric moisture in less than an hour. The maximum rates recorded in Table 1 (Appendix I) for 15-min. periods occasionally approach or exceed the greatest observed daily evaporation from free water surfaces. Many of the inequalities as well as the similarities displayed by those two phenomena are traceable to limitations governing atmospheric moisture capacity.

Under the extreme conditions immediately preceding a storm, with the temperature as high as 110° Fahr. at sea level, for example, and the air column closely approaching saturation, the moisture subject to precipitation is nearly 2.8 in. in the first mile above the base; 1.3 in. in the second mile; 0.6 in. in the third; and 0.3 in. above the 3-mile level, according to Table 3. For such a condition, a 5-in. depth of rainfall (Table 3) may be the attainable limit without renewal of the moisture supply by wind movements. Whether a multiple or only a fraction of that amount may be registered as precipitation is beyond present human knowledge unless the records of past performance may serve as a guide.

*In the Dictionary of Applied Physical Science, Vol. III, p. 61, is a chart displaying the data observed and derived by several carefully conducted series of investigations.

†As the portion of the moisture content at saturation which is subject to precipitation varies from nearly 50 to 75%, this is nearly the correct proportion of the total, shown in the preceding column.

Field observations recorded in Table 4 for atmospheric moisture capacities at widely separated stations have furnished a practical and satisfactory test for Table 3, whether applied to frigid, temperate, or torrid regions. In most instances both summer and winter conditions were observed.

Not all the moisture content of either the air or the soil is subject to removal by natural processes; a considerable percentage remains as residue continuously. The moisture that may be removed from the air column by precipitation during a storm is probably not more than one-half or three-fourths of the total capacity at saturation.

For various soil types the readily removable moisture may range from more than 90% for sand to less than 20% for heavy clay. The effective storage capacity and also the contribution to stream flow during dry seasons are reduced accordingly, and thus the opportunity for evaporation may be limited by what the soil will relinquish when the heat units and atmospheric capacity for moisture are both available.

It is evident that the normal rates of evaporation for various latitudes or for different climatological zones are such as would surcharge the atmosphere within a period of a month, or less, under any conceivable conditions, provided there is ample opportunity for evaporation from either free water surfaces or wet soil, or for transpiration from luxuriant vegetation and foliage. The surcharged atmosphere obtains relief either by increased temperature and moisture capacity, or by precipitation.

If proper allowance be made for the required interval of lag between the processes of evaporation and precipitation, together with the effects produced by progressive seasonal and local variations of temperature and relative humidity of the atmosphere, some of the characteristic rainfall habits may be explained, or, perhaps, they may be forecast. Likewise, the influence of barriers, whether they be mountains or masses of dense, cold atmosphere obstructing the path of moisture-laden air currents, can be partly evaluated.

The most dependable controls for such methods of analysis seem to be the long-period records kept by weather bureaus, supplemented by a consideration of the fundamental physical laws involved. Where only meager records are available, it seems advisable to attempt the expansion of fragmentary data in terms of what appears to be the attainable limiting conditions against which provision should be made in the design of waterways for a given locality. Table 1 (Appendix I) and Table 2 were compiled to furnish something of a background for interpreting the more detailed data which may be assembled for specific problems, in the same manner as previously used for hydrographic investigations.[3]

It appears that precipitation may vary either directly or inversely with evaporation, depending on local conditions which determine whether the moisture supply is steady or intermittent; whether the source is near-by or remote; whether the routes to be traversed by the winds are clear or obstructed.

[3] "Flood Flow Characteristics," *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 985.

both approaching and beyond the station in question; and whether the latent energy represented by the vapor content of the atmospheric column is capable of producing a violent, or only a moderate, disturbance upon release by condensation.

*The Energy of Vaporization and Condensation.*—The energy required to change 1 lb. of ice at 32° Fahr. to water amounts to 144 B. t. u., equivalent to the work of elevating that same weight 144 by 778 ft., or to a height of 21.2 miles. The same quantity of heat would raise 144 lb. of water from 60° Fahr. to 61°; or 1 lb. of water from 32 to nearly 176 degrees.

Evaporation of 1 lb. of water under average atmospheric pressure at sea level requires the expenditure of 1 069 B. t. u. at a temperature of 40°; 1 052 B. t. u. at 70°; or 1 036 B. t. u. at 100° Fahr. Thus, at ordinary temperatures and pressures, such as prevail while most of the process takes place, it requires approximately seven times as much energy to vaporize a given weight of water as to melt the same amount of ice; or if converted into units of work, it represents an expenditure that would elevate the same weight to a height of nearly 150 miles.

Because the relative weights of air and water vapor at equal temperatures are as 1.0 : 0.62, it is apparent that the presence of 3.0% by weight, or 4.8% by volume, of moisture to produce saturation at 90° Fahr., as shown by Table 3, will reduce the weight of the entire volume by 1.8% as long as condensation is delayed. A condition of marked instability, therefore, may result if opportunities for evaporation are alternately favorable and unfavorable. At 70° Fahr., 1%, and, at 110° Fahr., 3.4%, of variation in weight and consequent pressure may be due to the vapor content.

The condensation of 1 in. of rain releases the equivalent of 2 h.p.-hours of energy per sq. ft. of surface, or nearly 87 000 h.p.-hours per acre. If applied exclusively toward heating the first mile in height of air column above sea level, the resultant increase of temperature would be 30° Fahr., or more, depending on the density and humidity; and this thermal change would cause an expansion ranging from 6 to more than 10 per cent. The resulting buoyancy would be of the same order as that possessed by ice or logs floating in water.

Although it is improbable that all the latent energy released during a storm is devoted solely to heating a portion of the atmospheric column, it is definitely known that a large part of it induces energetic convection currents which continue until equilibrium is finally established or approached through ascent, expansion, cooling, intermixing, and condensation. Much of the heat is introduced into the soil by the absorption of rain water and thereby promotes bacterial activity, the release of soil fertility, and the rapid growth of vegetation, which is so noticeable after a storm, especially one that is prolonged and of only moderate intensity.

### Time Element Involved in Evaporation and Condensation

Pure, dry air may transmit solar radiation with losses of less than 10% when the sun is near the zenith. Other highly transparent substances of

equivalent mass, such as a 34-ft. depth of clear, placid water, or a 14-ft. thickness of the best grade of glass, behave similarly. The amount of energy delivered from the sun at such times is capable of evaporating nearly $\frac{1}{12}$ in. in depth of water every hour, or of melting $\frac{1}{2}$ in. in thickness of ice, or of raising the temperature of either a 6-in. layer of dry soil, or of a 1 000-ft. stratum in the lower atmosphere fully 25° Fahr. Thus, a few consecutive hours of intense sunshine would render the tropics and even the temperate zones unsuitable for most forms of organic life, were it not for the moderating influences of moisture and wind.

Fully 12 hours of very bright sunshine, or the combined action of persistent wind and moderate temperature, are required to evaporate 1 in. in depth from a free water surface. Such a rate is rarely exceeded except in shallow pools or in places exposed to vigorous wind movements. Condensation of the same quantity ordinarily occupies several hours, but in extreme cases precipitation, the culmination of the process, occurs within a few minutes in greater amount. Virtually, it is bulk delivery as opposed to the deliberate complexities of manufacturing.

The intimate knowledge and accurate interpretation of meteorological conditions which were so largely stimulated by the development of aviation, have gradually taken definite form, and one of the new departures, that is, official weather forecasts a full week in advance, is well within if not beyond the experimental stage. Thereby the major storm movements and the general tendencies on large areas are foretold with nearly the same degree of accuracy as the more detailed local weather forecasts have attained for small areas.

## Soils and Their Moisture Capacity

The products of rock-weathering ultimately become soils through changes wrought by micro-organisms with the assistance of climatic and biological forces. Prior to the bio-chemical alterations the decomposed or disintegrated material has not developed its character sufficiently to permit classification under soil types; it is regarded, therefore, as in the embryonic stage. As the biological activity extends only a few feet below the surface, and chemical, hydrolytic, thermal, and other disturbing influences are most pronounced in the same zone, the upper layer to a depth of 10 ft., or less, claims most of the attention of soil investigators.

*Recent Conceptions Concerning Soils.*—Since 1900 the foundation of a radically new conception of soil science has been established in Russia and developed in Europe and America, until it now occupies a major position commanding a broad field. Old ideas regarding the dominant influence of the parent ledge were abandoned after it was demonstrated that a given type of soil may develop from any of the most prominent varieties of rock magma, provided the environment is favorable. From this view has evolved the notion that soil is not a mere inert residue or product of decay, but a complex

entity, a creature of growth and culture with varying expressions of vitality. Its habits seem to reflect the influences of the temperature, rainfall, and drainage which governed its development, as well as that of lower forms of organic life which are so intimately associated with fertility and fruitfulness.

Carrying the simile still further, it has been aptly observed that the coarser granular particles constitute the framework or skeleton and determine the stability of the body structure. Again, the colloids combine the functions of tendons, muscles, linings, digestive system, and surplus tissue, for here the stores of essential minerals and other plant food lie quiescent until requisitioned by the circulatory system to supply the needs of vegetation.

There is a well-defined respiratory process by which oxygen is introduced and carbon dioxide removed; complexions of red, gray, brown, or black, disclose the degree of oxidation and hydration, and also the presence of iron or other coloring pigments that have survived the process of leaching. Here, as in organisms, impaired drainage facilities may produce a pronounced toxic condition. The living roots readily resist the soil digestive process, but the dead wood soon succumbs to the yeasts, moulds, and bacteria swarming within the colloids. Finally, soil degenerates under improper treatment and responds so gratefully to regular care and understanding that it seems like an expression of life and health, rather than of decay.[4]

## Soil Characteristics

A comparison of the desirable qualities or characteristics of soils brings forth striking contrasts. For example, the presence of considerable organic matter is objectionable in soil for structural foundation and highway purposes; and it is either beneficial or vitally essential in the case of soil for agricultural use and stream regulation. For example, the presence of considerable organic matter is objectionable in the first case, and either beneficial or vitally essential in the second. On the other hand, high percentages of coarse, inert, granular fragments of rock are desirable for sustaining either structures or traffic and also for regulating run-off, inasmuch as stability and ready drainage facilities are among the prime requisites. These considerations, however, do not govern in farming operations; there, the sieve-like structure of coarse, gravelly, or sandy soil has become almost a synonym for sterility or lean production.

Where the only available sub-grade material is a fertile soil, it requires some sort of treatment to render it suitable for sustaining either structures or traffic. Dragging, rolling, or other manipulation while the soil is wet may afford improved stability and resistance to accessions of moisture. Both the results and the methods used are contrary to recommended practice in agriculture or in the maintenance of water-sheds to regulate run-off, for in such

[4] "Soils and Civilization," by Milton Whitney, Chf. of the Bureau of Soils, U. S. Dept. of Agriculture, p. 25, "The Soil as a Living Thing."

activities it is considered that the permeability, the normal capillary structure, and the organic life of the soil should be maintained and not destroyed. The readiness with which an overturned bucket of water is absorbed in a meadow or lawn, in contrast with its behavior on a well-trodden pathway where saturation is long delayed and where there is never danger of miring, illustrates the difference between productive soils under a cover of vegetation and the same materials after puddling and compression, erosion and baking, have rendered them sterile and inert.

It is an unusually close-textured soil that cannot absorb and temporarily hold 1 in. of rainfall for each foot in depth of the soil deposit, provided no previous saturation, freezing, baking, or mechanical compaction has occurred to seal the inlets. In the deep soils traversed by irrigation systems of the West, it is customary to sustain a loss of 10 to 20 in. of water daily over the entire wetted perimeter of earth canals, regularly throughout the season. In humid regions only unusual soil structure, such as occurs in coarse sandy or glacial deposits, would be capable of comparable behavior; yet in lesser degree all soils of close texture may function similarly, especially if covered with dense vegetation.

For ordinary rates of rainfall the toll taken by vegetation and soil to prevent or regulate run-off is much greater than the capacity of detention basins usually designed and provided by works of Man. The flood volume recorded in Lake Champlain within a week following the unusually severe storms of early November, 1927, was not more than one-half the actual precipitation as estimated by several independent investigators, including official observers. For restricted areas near the head-waters, nearly 90% appeared as run-off, but this may have been further depleted on its way to distant outlets.

*Soil Classifications.*—Soils are sometimes classified on a chemical basis, as silicate, carbonate, sulfate, or ferruginous deposits, each with suitable subdivisions. Another system utilizes the manner of deposition, as residual, transported, alluvial, colluvial, aeolian, or glacial, with subdivisions according to parent sources, as quartzite, granite, dolomite, or basalt.

The Russian scientist, Glinka, has proposed a general classification based on the moisture conditions under which the types were developed, whether excessive, optimum, average, moderate, or insufficient; with sub-classes such as tundra, podsol, chernozem, prairie, gray desert, laterite, and red loam, each identified by color, position, texture, composition, and details regarding the formation generally.

The United States Department of Agriculture, through the Bureau of Soils, has developed what appears to be the most logical and comprehensive classification yet devised, incorporating the outstanding features of all other important systems, each in its natural position. The primary category is based on the presence or absence of calcium carbonate accumulations; the second on the degree of oxidation, stage of leaching, formation of sesqui-

oxides, and the differences in organic content. The third category identifies the soil type, such as laterite, podsol, or chernozem; the fourth has to do with the "soil profile", that is whether or not the characteristic changes have developed at the various "horizons", or depths below the ground surface, from top-soil to sub-soil.

Further subdivision deals with geographical regions and soil provinces, as Piedmont, Upland Valley, or Coastal; the locality where a given type was first surveyed and classified, as the Upshur, Miami, or Volusian series; and, finally, the texture and composition are described, as gravelly loam, light silty clay, or heavy gumbo.

The results already achieved in the United States as well as abroad justify the belief that this system of classification may be adopted generally. Every major and minor series or type falls into its proper place in that system after a thorough field study and occasional laboratory tests have been completed.

*Utility of Soil Surveys and Classification.*—The obvious utility of soil analysis, research, surveys, and classification is to extend the horizon of knowledge and to make the best use of what has been gathered heretofore. Wherever a soil type is identified an intelligent judgment may be formed regarding its genesis and development, the climatic, rainfall, and drainage habits that prevailed, and the vegetation sustained during the progressive stages of its growth. In the brief period since soil science has been recognized adequately, it has rendered valuable service to agriculture in all its phases, to commerce, to the manufacturing industry, to water supply, to flood protection, and to the most extensive and important highway development yet undertaken.

What promises to be one of the most notable steps forward was inaugurated by the U. S. Bureau of Public Roads as sub-grade investigations. The work has been carried on in co-operation with various State highway departments and colleges. The net result thus far has been to narrow the problem down to the identification and treatment or the elimination of harmful elements. Inasmuch as the ordinary failures of pavements that are traceable in any manner to unstable sub-grades represent but a small proportion of the total mileage, attention has been concentrated on these sections. Further applications for soil science are yet to be realized in the broad fields of structural and foundation design, drainage, control of surface run-off and underground water supplies, crop production without serious depletion of fertility, and all lines of endeavor that depend on soil materials or properties.

Illustrative of the clues to soil characteristics which have long been familiar to even casual observers, a rank growth or a precarious one of either arrow-weeds or bud-sage, salt-grass or blue-grass, cactus or willows, may publish more information concerning the chemical analysis, texture, water supply, and drainage habits of the land than could be conveyed on several pages. If the principal vegetation is scrub cedar of the uplands, swamp cedar, or the giant redwood, radically different conditions are known to govern.

## Classification of Precipitation Patterns

The time and labor of assembling and reducing the summarized precipitation characteristics presented in Table 1 (Appendix I) may prove to be meager as compared with what will be required to develop an adequate appraisal and interpretation of the data contained therein.

A tentative classification is presented in Table 5, in which the first or primary basis of division depends on climatological zones, approximately defined by parallels of latitude. The irregularities introduced by such influences as ocean currents and prevailing winds, as illustrated in Siberia, Labrador, and the Scandinavian Peninsula, for example, seem to be fully as significant and important as the similarities displayed by other groups of stations. The second and third categories have to do with distances inland and altitude, respectively; and, finally, the representative stations to show both the range of habits and also the average behavior for specified conditions, are arranged according to the amount of either annual or monthly rainfall. Other selections might be made to display somewhat greater or less concordance than appears in Table 5, wherein both length and completeness of record were taken into account.

Outstanding features of Table 1 (Appendix I), and Table 5 are the manifestations of progressive increase of moisture capacity with temperature. It is notable that the greatest observed intensity of rainfall occurs in the sub-tropical, and not in the equatorial regions. Evidently, this is not due to lack of atmospheric moisture, but to the fact that some of the conditions necessary to the violent relinquishing of moisture are not to be encountered near the equator. For example, the polar fronts and cold air currents and icebergs are all unheard of in lower latitudes for the same identical reasons. Special situations might be encountered, however, in which the condensing medium would be supplied from the sub-zero temperature zones in the upper atmosphere, if it were not for the regular daily relief afforded by the mid-day showers of the tropics; and it is conceivable that rates of precipitation might occur during a brief period as intense as have been registered elsewhere.

The tabulations plainly indicate that there are fairly definite limiting conditions and rates of rainfall appurtenant to the various climatological zones. There are typical rainfall patterns displayed in the percentage columns of Table 1 (Appendix I), which may be utilized for combining fragmentary records, or for supplying missing data under proper controls.

## Application to Practical Problems

In the solution of practical problems, the greatest needs are for more basic data and for a better means of interpreting those already available.

Inquiries as to what may be expected in the way of rainfall and run-off habits in a given locality are too often answered by reference to voluminous

tabulations, when summarized data such as those in Table 1 (Appendix I) would serve more satisfactorily.

Arrangement of a long series of natural phenomena according to magnitude of the observed quantities, such as are used in precipitation and run-off records, invariably results in a crowding near the mean values, and a thinning out toward the extremes, suggesting a mass distribution like that of a cone or of a pyramid, in which the base represents the mean and the apex, either the maximum or the minimum. It is naturally expected that the longer the period of record, the wider is the interval between the mean and either the maximum or the minimum. Because the 500-year or other long-period maximum must fall in the record of some decade, care should be taken to investigate such a possibility. When such happenings are properly taken into account, some interesting and useful relations become apparent regarding periodic maxima and frequency curves:

*First.*—The only direct relations to be observed consistently among station records are such as may be ascribed either to contiguity or to similarity of climatic conditions.

*Second.*—No direct relation is traceable between rainfall and sunspot periodicity (11 to 12 years), which closely corresponds to the time of revolution about the sun (11.86 years) of the planet, Jupiter, representing 71% of the total known mass of the solar planetary system. Seven of the longest known annual precipitation records are platted in Fig. 2, for convenient comparison. The occasional similarities, contrasts, and synchronisms therein displayed, seem to indicate endless variety rather than conformity to any generalization.

*Third.*—The mean monthly or the mean annual precipitation, together with the maxima for corresponding periods to be expected during average intervals of 10 years, 50 years, and 250 years, seems to form a simple arithmetical progression, while the related time intervals, namely, 2, 10, 50, and 250 years, form a geometrical progression. Fig. 3 illustrates for the yearly precipitation how nearly the straight-line relation holds for frequency curves when they are thus plotted on semi-logarithmic paper. Similar results are found for monthly periods.

*Fourth.*—The ten percentage columns of Table 1 (Appendix I) seem to provide generally ascending series of either geometrical or arithmetical progression, from left to right. The quantities in Column (1), headed "Mean Daily Intensity on Rainfall Days", are but the reciprocals of the average number of rainy days per year, expressed in percentage. Thus, for stations with 90 days of rainfall per annum, the mean daily intensity is 1.1% of the total mean annual precipitation. The quantities in Column (1) seem to be significant and important when considered in connection with the remaining nine columns. In general, this percentage is numerically equal to the maximum rainfall to be expected in a 3-min. period.

Since the beginning of these investigations and the assembling of the foregoing data, many opportunities have been presented for practical tests of

methods herein advocated. For example, preliminary estimates were made for the waterways required in connection with current projects, mainly from consideration of rainfall habits and soil texture, classification, and covering. Later, they were compared with the final estimates, made after detailed study of the water-shed, run-off records, and all other available data, with satisfactory results.

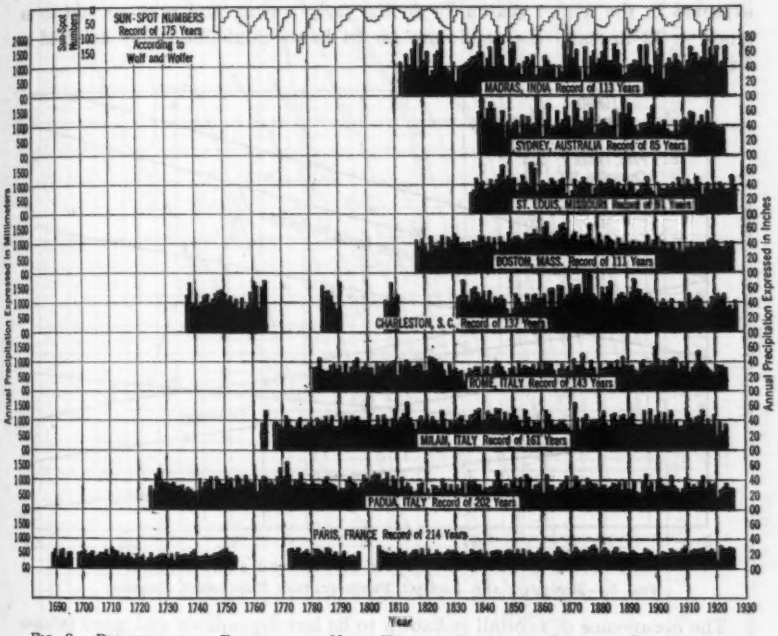

FIG. 2.—PRECIPITATION RECORDS AT NINE TYPICAL STATIONS, SHOWING RELATION TO SUNSPOT NUMBERS

Application to a foreign problem is afforded by the Habra Dam disaster of November 26, 1927, in the Province of Oran, Northern Algeria. This dam had previously failed on March 10, 1872, in the year following its construction; and again on December 16, 1881, after reconstruction and enlargement of the spillway, the fatalities in this instance amounting to 400.[5]

The scarcity or utter absence of meteorological and hydrographic records are admittedly among the primary causes of the recurrent disasters. Through costly experience it has now been demonstrated that the 3 085 sq. miles of water-shed above the dam site are reasonably capable of yielding run-off at the rate of 20 sec-ft. per sq. mile instead of only one-fourth or one-half of that amount as assumed for the original construction and reconstruction, respectively.

[5] "The Failure of the Habra Dam, Algeria," *Le Génie Civil*, March 17, 1928, p. 256.

There is enough similarity observable in the rainfall patterns for Italian, French, and Spanish stations near the Mediterranean Coast, to permit expansion of the records for North Africa by use of such definite data as have long been available for the Ports of Tunis, Algiers, and Tangiers. The annual rainfall to be expected in the vicinity of Oran and Perregaux, in the Habra Basin, is known to range usually from 20 to 28 in.; the monthly maximum is to be expected in the winter season, or in the early spring, and may amount to as much as 12 in.; and the maximum for 24 hours might be safely assumed as 6 in.

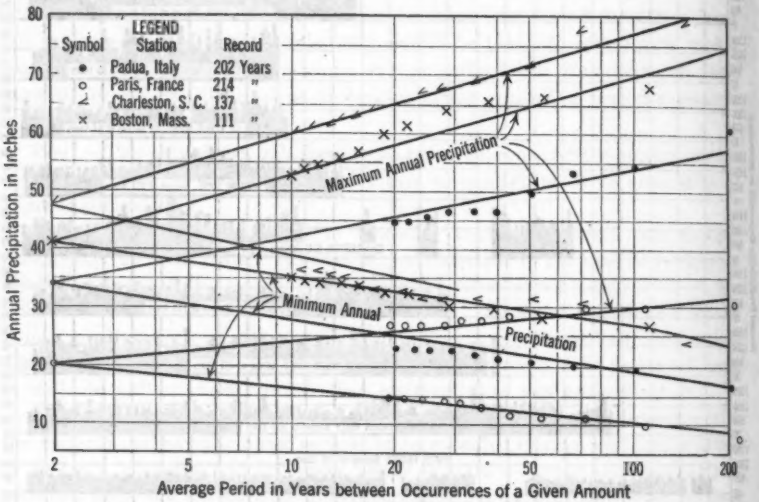

FIG. 3.—MONTHLY AND ANNUAL PRECIPITATION FREQUENCY CURVES

The occurrence of rainfall is known to be less dependable and more intense in Algeria than on the northern shores of the Mediterranean, just as should be expected when the desert character of the hinterland is taken into account. Finally, the Tiber River in Italy and the rivers of Eastern Spain should have afforded an index as to the expected run-off from the Habra Basin capable of governing an adequate design for the spillway that has recently failed for the third successive time.

Illustrative of the recommended method of approach for such practical problems, the meteorological records of the most nearly adjacent and comparable stations were reviewed in their summarized form as used in Table 1 (Appendix I), and supplemented by such literature and data as were available for the locality, in order to form a fair conception of the run-off habits to be expected under extreme conditions, as well as the average prevailing in that locality. Other published data[6] afford a number of examples which may be

[6] "Flood Flow Characteristics," *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1003, Table 2 (Appendix I).

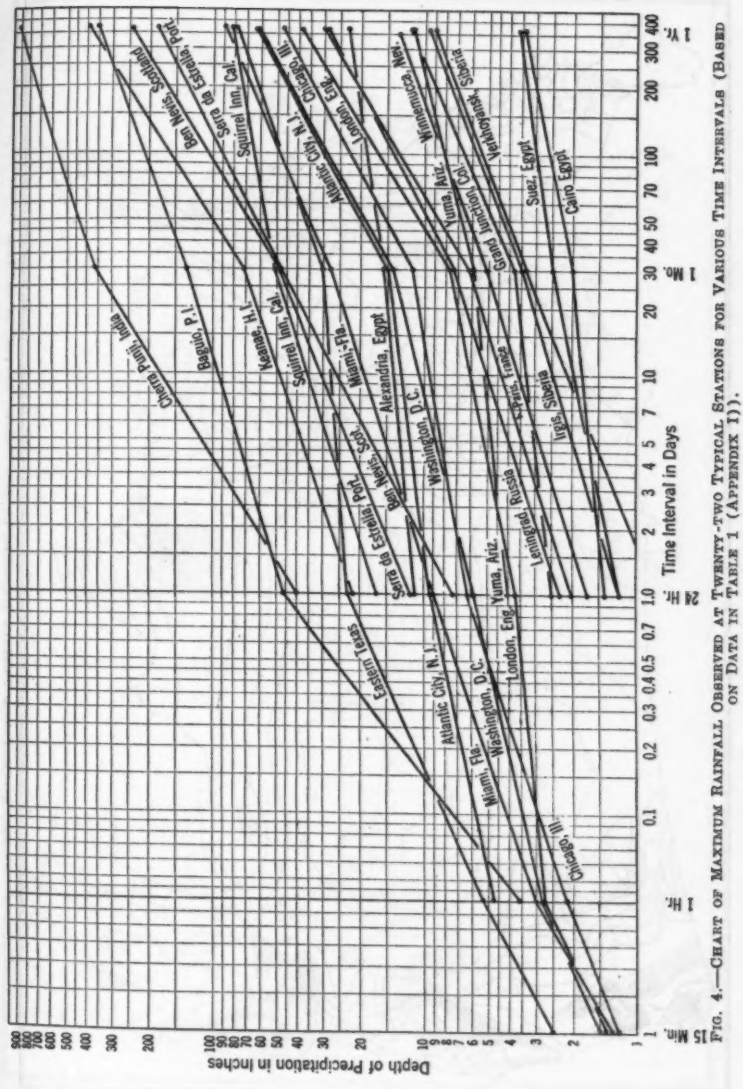

FIG. 4.—CHART OF MAXIMUM RAINFALL OBSERVED AT TWENTY-TWO TYPICAL STATIONS FOR VARIOUS TIME INTERVALS (BASED ON DATA IN TABLE 1 (APPENDIX 1)).

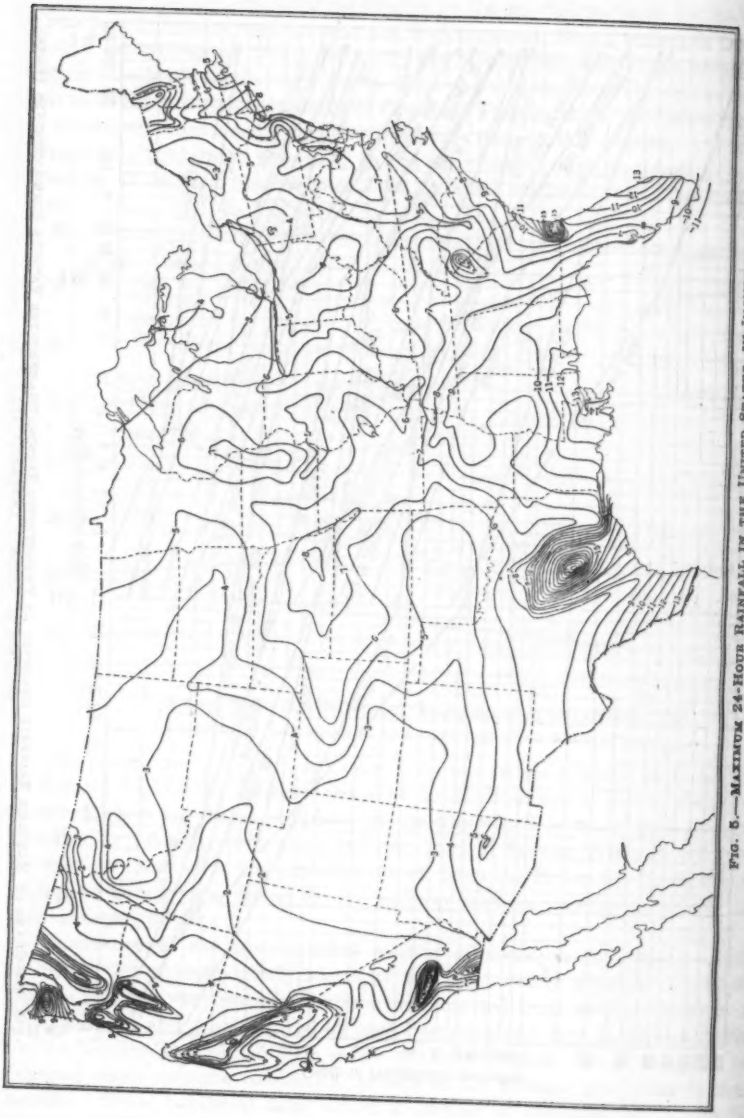

FIG. 5.—MAXIMUM 24-HOUR RAINFALL IN THE UNITED STATES, IN INCHES.

utilized for comparisons if due allowance be made for differences in the temperature, humidity, seasonal habits, and wind directions during stormy periods; in the soil, topography, and shape of basin; and in the slope and other influences that may determine the retention or the run-off during and following a storm.

Obviously, for an estimate of stream discharge from the Habra River of Northern Algeria, the records from some of the Mediterranean coastal rivers, or from Virginia, Arkansas, and California, would be more helpful than those from high latitudes and rigorous climates, or far removed from desert areas. Neither ice nor snow accumulations nor deeply frozen soil enter into the problem for Northern Africa; the periodic aridity produces a marked effect on both the soil structure and the character of vegetation, and the run-off habits of drainage channels are modified accordingly.

### Run-Off Due to Thawing

Where the run-off resulting from a sudden thaw is an important consideration, the limiting rates for which provision should be made, may be estimated by reference to the seasons of the year when both high temperatures and snow, ice, or hail accumulations have been observed or may reasonably be expected, together with the relative effects of sunshine, wind, and rain. Under the most favorable conditions conceivable for mid-latitudes, with the air clear and dry and the sun near the zenith, nearly ½ in. of ice may be melted per hour by direct sunshine. Chinook winds may account for the same maximum 24-hour rate of melting as has been observed for solar radiation; but the hourly rate is considerably less, and appreciable percentages of the released moisture are disposed of by evaporation, and, therefore, do not contribute directly to run-off.

Again, if the maximum conceivable flood conditions seem to involve warm rains on either snow, ice, or frozen ground, it appears that the volume thus contributed by thawing cannot exceed one-third the rain volume at that time; for if the temperature of rain water be reduced from 80° Fahr. to the freezing point by contact with ice, it would release not more than one-third its weight of frozen moisture, as determined by the ratio of the 48 heat units extracted to the 144 required for melting ice, to which reference has already been made; and the assumed limits are seldom if ever attained.

Each application of the principles and methods herein set forth should receive individual treatment; but the controls are essentially collective and require mature judgment, observation, and experience for the best results.

### Graphical Representation of Rainfall Characteristics

The maximum rates of rainfall that have been observed as typical stations representing almost the entire range of habits for the stations listed in Table 1 (Appendix I), are illustrated in Fig. 4. The platting on multi-phase logarithmic diagrams brings out not only the similarities, but also the diver-

gencies of precipitation patterns and trends. Figs. 5 and 6 portray the maximum observed depths of precipitation in 24 hours and in one calendar month, respectively, for the United States, based on the data of Table 1 (Appendix I). Fig. 7 is a graphical representation of the maximum monthly rainfall over the entire earth so far as is disclosed by the data contained in Table 1 (Appendix I).

It is readily recognized that the inclusion of additional station records and the use of a larger scale for mapping might introduce important revisions. The curves drawn on the Mercator projection, however, may serve as generalizations and may assist in visualizing some of the rainfall characteristics of the world.

## Conclusions

1.—The precipitation to be reasonably expected at a given place, together with the run-off resulting therefrom, may be regarded as but the expression of certain physical forces and habits, explainable in the main on the basis of known scientific laws and principles applied to the source of supply and to the paths traversed by winds and drainage channels.

2.—The factors responsible for both rainfall and run-off are fairly well defined; most of the earth's surface has been explored; the courses of ocean currents and the prevalent paths of storms have been charted; and the potentialities of recurrent storm movements have been recorded in terms of barometric pressures, precipitation, wind velocities, and flood volumes.

3.—Wherever meteorological and hydrographic records are available, approximations may be made with varying degrees of dependability as to both the ordinary habits and the extremes of behavior against which provision should be made. By utilizing the long-period records as controls, the brief or fragmentary data may be interpreted more effectively.

4.—Precipitation and run-off habits which govern the design of waterways display characteristics definite enough to be classified, and they are known or may be derived from well co-ordinated records within nearly the same range of accuracy as is ordinarily attained for strength of structural materials.

5.—Many of the catastrophes resulting from storms and floods should be recognized as preventable accidents, and public works should be inaugurated to reduce such hazards.

TABLE 1.

| Station No. | Station | Elevation above sea, in feet. | Years of Record. For day or sun. | Years of Record. For month and year. | Years of Record. Last day [illegible] | Maximum Observed Precipitation. Number of Minutes. 5 | 15 | 60. | Maximum Observed Precipitation. Day of 24 hours. | Maximum Observed Precipitation. Month. | Annual Precipitation. Minimum. | Annual Precipitation. Mean. | Annual Precipitation. Maximum. | Annual Precipitation. Mean daily excess or deficiency. | Observed Precipitation, in Percentages of Mean Annual Rainfall. Maximum During Short Periods. Number of Minutes. 5. | 15. | 60. | Observed Precipitation, in Percentages of Mean Annual Rainfall. Mean for month of maximum rainfall. | Maximum. In 24 hours. | Maximum. In any single month. | Annual. Minimum. | Annual. Mean. | Annual. Maximum. | Mean subnormal. |

## DISCUSSION

GEORGE S. BLISS,[7] ESQ. (by letter).—The outstanding features of interest in this paper are the ten columns of percentage values in the tabulated matter and the discussion of precipitation patterns. The percentage columns shed new light on some old problems by placing them in new settings.

In the discussion of precipitation patterns a little more prominence might have been given to the part played by topography, which seems to be one of the major factors. Without more or less rugged topography the other factors lose much of their effectiveness. For example, with a topographic map of Pennsylvania, it is entirely feasible for one versed in the meteorology of this section to prepare a fairly accurate outline of the rainfall distribution and to estimate closely the relative differences between the wettest and dryest regions of the State without the aid of precipitation data. The author's deductions from generally accepted meteorological facts and theories seem good.

Steep barometric gradients are not always accompanied by steep temperature gradients. In the ordinary cyclonic disturbances it seems to require a combination of both conditions to produce maximum wind velocities. In instances where the temperature gradient is comparatively flat, the wind velocities are usually moderate despite fairly steep pressure gradients. The greatest wind velocities known are in tornado funnels, which are solely the result of great differences in temperature of adjacent air masses. The extremely steep barometric gradients in the funnels are results of, rather than causes of, the violent air circulations.

If there is any relation between variations in precipitation and sunspot numbers it is completely overshadowed in localities, or over small areas, by accidental causes. It could be detected only by computing mean monthly and annual rainfall over vast areas, such as a continent or an entire hemisphere. Variations in solar radiation, if there be such, are completely absorbed in the general circulation of the atmosphere, and are not in evidence in the temperature records of any particular region.

This paper as a whole seems to apply more particularly to the problems of flood forecasting, and less directly to those of flood control. Just to the extent that calculations for the latter are based on such stern realities as river-gauge heights and stream-discharge measurements, the variable factors leading up to that stage are eliminated, and accurately so.

BREHON B. SOMERVELL,[8] M. AM. SOC. C. E. (by letter).—The author has assembled a mass of basic data which should be of value for the general study of the factors responsible for rainfall and the corresponding run-off. Covering as they do the entire globe, these data should be helpful in analyzing any particular water-shed by comparison with other water-sheds.

Neither the data presented nor other generalities will suffice for a thorough study of a particular water-shed. If stream-flow records are lacking, considerable judgment must be used in drawing conclusions as to the resulting

[7] Senior Meteorologist, U. S. Weather Bureau, Philadelphia, Pa.
[8] Maj., Corps of Engrs., U. S. A., Memphis, Tenn.

run-off because there are a number of factors affecting run-off, and also because there are different methods for combining these factors.

The factors themselves are fairly definitely known, and the effect of a definite factor, or a definite combination of factors, on the run-off to be expected from a definite amount of precipitation, can be predicted without too great an error. No method is known, however, whereby engineers can predict which combination of factors will occur at a specific time, and, consequently, estimates as to run-off will always be subject to considerable error for water-sheds of any appreciable size.

In studying an individual stream, the water-power resources, its navigable capacity, or the menace of its floods, the engineer is concerned particularly with the actual past performance of the stream. A mean of past performances is not sufficient, nor is the record from only one station of great value. Storage must be provided for low-water periods, during which the stream will not supply sufficient water for power or navigation, and storage or other means of flood control must be provided for the high-water period also when valley storage is not sufficient. For these purposes monthly quantities of flow are the smallest increments that may be used safely. If there is no record of these flows, so that they must be computed from rainfall data, then the records from all stations within the area under investigation should be included. For example, in the study of the Potomac River as a source of power the following observations are noted:

| | Inches. |
|---|---|
| Mean Annual Precipitation, Potomac River Basin: | |
| From U. S. Engineer Office, approximately | 41 |
| From Table 1 (Appendix I), (Station 75, Column (13)), Washington, D. C. | 40.5 |
| From Table 1 (Appendix I), (Station 76, Column (13)), Washington, D. C. | 42.2 |
| Maximum Annual Precipitation Recorded in the Potomac River Basin: | |
| Bayard, W. Va., 1926 | 89.01 |
| Maximum Annual Precipitation Recorded for Potomac River Basin in Table 1 (Appendix I): | |
| Washington, D. C. (Station 75, Column (14)) | 61.3 |
| Washington, D. C. (Station 76, Column (14)) | 61.3 |
| Elkins, W. Va. (Station 74, Column (14)) | 65.4 |
| Minimum Annual Precipitation Recorded in Potomac River Basin: | |
| Western Port, Md., 1895 | 12.71 |
| Minimum Annual Precipitation from Table 1 (Appendix I): | |
| Washington, D. C. (Station 75, Column (12)) | 18.8 |
| Washington, D. C. (Station 72 (Column (12)) | 30.8 |
| Elkins, W. Va. (Station 74, Column (12)) | 38.8 |

Maximum, minimum, and average tabulations at single stations are not conclusive as to conditions even in a relatively small surrounding area, and

cannot be used with accuracy in the investigation of a near-by drainage area for water-power potentialities or flood-control studies.

As an instance the drainage basin of the Potomac River is covered in Table 1 (Appendix I) by the stations at Washington, D. C., and Elkins, W. Va. The maximum annual precipitation is recorded at Elkins, as 65.4 in. Actually, the maximum annual precipitation recorded within the Potomac River drainage basin was 89.01 in. at Bayard, W. Va., in 1926, a difference of approximately 24 in.

The same situation occurs in the minimum annual precipitation recorded as 18.8 in. at Washington, D. C., in Table 1 (Appendix I). Western Port, Md., however, in 1895, recorded an annual precipitation of 12.71 in., 6 in. less than the minimum recorded in Table 1 (Appendix I). An entirely different picture may thus be presented, depending upon the stations selected.

From these remarks it will be noted that although the mean for the water-shed derived from a large number of stations approximates fairly closely that given by Mr. Jarvis in his tables for the station at Washington, his maxima and minima are far from those which have been recorded at other stations within the past and also far from the maxima and minima applying to the basin as a whole.

In the study of large water-sheds involving several hundred thousand square miles, the data given in Table 1 (Appendix I) may furnish means, maxima, and minima closely approximating those which might be obtained from a much larger list of stations within the same area. In no case, however, is it believed that one station could be used with any degree of accuracy in a design of works for flood control, power, and navigation.

In other words, comprehensive summaries, such as the author has presented, aid one in studying the local problem by quickly giving one a broader geographical picture of the rainfall phenomena. They may keep one from drawing false general conclusions from limited local data and may lead the way to additional pertinent information. They do fall short, however, of giving those data essential to reliable conclusions as to the solution of a particular problem.

Jesse W. Shuman,[9] M. Am. Soc. C. E. (by letter).—This paper is a valuable contribution to the subject, with the points well brought out and the conclusions carefully worded. Undoubtedly, the views expressed are a résumé of the current opinions of both meteorologists and hydrologists. The attitude of the former is reflected in the statement, "no direct relation is traceable between rainfall and sunspot periodicity * * *"; and the attitude of the latter is indicated by the methods suggested for study of the rainfall data by means of frequency curves, the consideration of floods, etc.

Meteorologists are quite aware of the cycles in weather phenomena, but, in general, they make no application of this knowledge, probably because the day-to-day or month-to-month variation in any of the generally used meteorological data is negligible. Occasionally, papers appear in the *Monthly Weather Review* that deal with this subject authoritatively, from the viewpoint of meteorologists

[9] Secy-Treas., Power Eng. Co., Minneapolis, Minn.

and mathematicians as well as "dyed in the wool" hydrologists. Stripped of all their involved mathematics, meteorological terms, and background, the crux of these papers is, that by proper treatment of sunspot numbers and rainfall or run-off data, a relationship does exist, which is easily discernible. The papers also show that, while these cyclic variations are negligible in their effect from day to day as to current weather changes, nevertheless, their effect is cumulative and works great changes in run-off, lake levels, etc.

The writer does not hereby intend to decry the work of the author; rather he wishes to show in what way the valuable data assembled by Mr. Jarvis can be further considered and used to great profit.

The author's Fig. 2 compares a graph of sunspot numbers with graphs of several rainfall stations. From an inspection of the graphs, Mr. Jarvis draws the conclusion that there is no traceable relation between the sunspots and the rainfall. The method of comparison here used is perfectly standard in its application, and it is readily admitted that, with the graphs as drawn and located, there is no easily recognizable relation.

In Fig. 8, the same data for sunspot numbers are used,[10] and graphs of rainfall at Milan, Italy, New Orleans, La., Charleston, S. C., and Greenwich, England, are shown. In Fig. 2 the sunspot numbers are inverted, with zero numbers at the top; whereas Fig. 8 shows the zero numbers at the bottom. Furthermore, Fig. 8 has a much larger vertical scale. After plotting all the sunspot numbers (the mean Wolf and Wolfer provisional number for the year) for the entire record, a smooth line is drawn through the plotted points. This yields the series of loops shown. This curve, thus far, is identical with Fig. 2, except that it is inverted. Each peak or crest represents maximum sunspot numbers, and the troughs represent minimum sunspot numbers. When viewed in this state, there is no apparent relation with rainfall. However, the curve may be further reduced. Divide the distance between each peak and trough (as at 1 and 2) with a dot; then pass a smooth line, Curve *B*, through the dots. This curve is the well-known Bruckner cycle; it is merely the median line traced through the smoothed sunspot numbers, which is the same line one would obtain if the sunspot numbers graph were repeatedly integrated. The peaks of this cycle represent, of course, relatively higher sunspot numbers. They occurred in 1787, 1803, 1837, 1870, 1893, and 1917.

Bruckner's discovery of this cycle was accomplished from studies[11] (mostly of European data) of secular variation of the Caspian Sea; lakes and seas without outlet; river heights; precipitation; atmospheric pressure; temperature; and times of grape harvest.

Although suspecting a relation between solar variation and terrestrial phenomena, Bruckner's efforts in this direction were unsuccessful. He simply reduced his statistical data by the use of five-year running means, and this method is insufficient to segregate the cycles.

Meteorologists discarded the cycle because it gave no reliable clue as to present-day variation in weather; and, further, because there was apparently no connection between it and any great "cause". With the advent, however,

[10] From *World Weather Review* and *Monthly Weather Review*.

[11] "Klimaschwankungen seit 1700," 1890, Vienna.

of the publications of the U. S. Weather Bureau, methods of analysis, with examples and illustrations, were given, showing more clearly the nature of the Bruckner cycle.

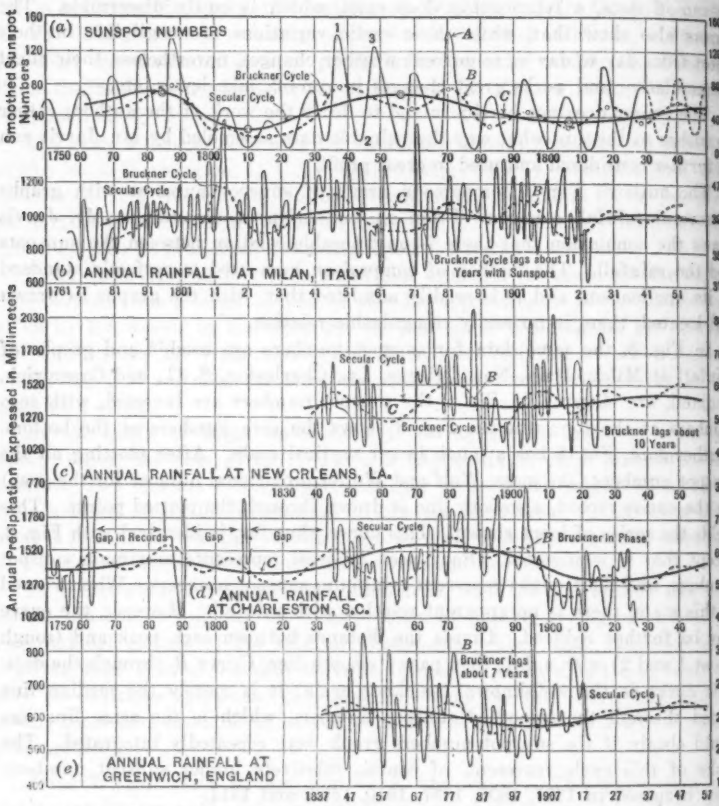

FIG. 8.—COMPARISON OF BRUCKNER CYCLES FOR SUNSPOT NUMBERS WITH CYCLES OF MAXIMUM RAINFALL

This cycle is now known to have a periodicity of about 22.6 years (crest to crest), superimposed upon a longer cycle called the Secular cycle. According to "Reports of the Conference on Cycles",[12] Hale's double sunspot period of about 22.5 years has been faithfully recurring (with slight variation) since 1810.6 for sunspot minima, and since 1816.4 for sunspot maxima. These cycles provide a very fair basis for predicting that 1946 will be a year of minimum sunspots; and also that 1951 will be a year of maximum sunspots. Using the same period of 22.6 years, and working from the sunspot minimum of 1913.6, the occurrence of the next probable sunspot minimum is predicted in 1936. These future periods have been shown extended on Fig. 8 (*a*).

[12] Carnegie Institution of Washington, 1929.

The Secular cycle is the next longer swing cycle mentioned by Bruckner (see Curve *C*, Fig. 8). This cycle is also variable in length, the last three periods being estimated at 70, 60, and 90 years, or an average of about 73 years. The cycle was high in 1855 and low about 1906. It is now trending upward toward a peak which may occur about 1945 to 1950.

Thus, in the provisional sunspot numbers, the value changes enormously from month to month, although the mean annual value has a periodicity of about 22.6 years from one maximum to the second next maximum. There are several cycles in these sunspot numbers, but the most important, for the present purpose, are the Bruckner and the Secular cycles. The result is to provide a cycle or pattern curve, constructed from sunspot numbers, and the next task is to show what use can be made with it.

Refer now to the rainfall graphs in Fig. 8. Of course, it is recognized that a single gauge does not truly register the rainfall at any district; that, in order to have an accurate measure, it would be necessary to have several gauges distributed over the district. When the data from several stations are averaged, the fortuitous storms are more or less "ironed out". Where only one station is considered, as in Figs. 2 and 8, the cycles may not emerge as clearly as they would if the graph were made up of data averaged over an area of several hundred square miles. On the other hand, if too large an area is taken, the data at one end or part of the district may neutralize those of another section, and one may secure no recognizable cycles. Preferably, then, eight or ten Weather Bureau rainfall stations should be included, and their data should be averaged. After one has gained experience in this type of analysis, it is possible to trace in the cycles in the data of a single rainfall station, as is done in Fig. 8.

Consider the graph of Milan rainfall (Fig. 8(*b*)). Here is a long record that, by proper treatment of its data, can be made to show both the Bruckner and Secular cycles. The treatment consists, essentially, of smoothing processes, and separation of the original graph into its component parts.

Assume, therefore, that these processes have been gone through with the Milan rainfall data and that, finally, the Bruckner cycle has been derived. Plot this cycle in the original graph, and then compare the graph with that of the sunspot numbers. In order to get the best synchronism between the Bruckner cycles in the two graphs, it will be necessary to set 1881 on the Milan graph on the 1870 ordinate of the sunspot graph. No attention is given to the amplitudes of the cycles; only the synchronism of the peaks and depressions is important. Fig. 8 shows that the trend in rainfall at Milan lags behind that of the sunspot numbers by about eleven years. If one looks at the Milan graph trying not to see any cycles, it seems only like a series of oscillating values, with no law or order. With the cycles drawn in, however, it certainly is obvious that, in general, the trend of wet and dry periods is in accordance with the "ups" and "downs" of the cycles.

In attempting to compare rainfall or run-off graphs with the comparison curve, that is, with the sunspot Bruckner cycle, the data of one cannot be compared with the current data of the other; there may be a lag or a lead; only occasionally are both sets of data in phase with each other. Bruckner

thought that the phase of his cycle was the same all over the world, but now it is known that the phase varies, depending on the geographic locality; that is, along the Atlantic Coast, at Boston, Charleston, etc., the trend of rainfall is about in phase with the sunspot numbers. Toward the West, however, the phase begins to lag, until a maximum lag occurs at the Pacific Coast. The phase may be different even within the confines of a single State. The prime requisite, therefore, in making comparisons of rainfall graphs is to determine first the phase of their trends.

The Secular cycle in the Milan graph is high in 1855 and low in 1906, the same as it is in the sunspot graph, because the phase of this cycle seems to be the same all over the world. Fig. 8(*b*) shows where the highest values for total annual rainfall occurred; that is, from 1841 to 1851, which is at the crest of the Bruckner, and near the crest of the Secular cycles. One expects higher values at or near the crests of these cycles, and, of course, lower values at the troughs. The graph indicates that the Bruckner cycle is the major control (because such low values occurred due to the Bruckner trough in 1861 to 1871, even if this period was very near to crest of the Secular cycle). A Bruckner crest is indicated in 1930, so that moisture conditions should now be above normal; and the next great wet period is indicated about 1945 to 1955.

In Fig. 8(*c*) the Secular cycle of rainfall in New Orleans is quite flat, with small amplitude. The Bruckner cycle is responsible for the great swings in moisture conditions in this case. Note that 1880 of the New Orleans scale is set on the 1870-year ordinate of the sunspot graph, thus indicating a lag of about ten years at that point.

In Fig. 8(*d*) the Bruckner cycle for rainfall at Charleston, S. C., is in phase with the sunspots trend, as indicated. The maximum wet period of the record occurred after the crest of the Secular cycle. The graph shows a trough of the Bruckner cycle at 1929, indicating a control toward lower rainfall values. Since there has been such a great drop from 1924 to 1927, the rainfall for 1928 is more than likely to be quite high. A study of rainfall records shows that Nature tends to preserve its balance, as it were; and that extreme values are likely to be followed by extreme values of opposite sign the following year or period.

Finally, Fig. 8(*e*) is for the rainfall at Greenwich, England; the lag is about seven years. The Bruckner cycle was at crest in 1927, indicating moisture conditions above normal. These few examples should suffice to show that:

(1) Rainfall has a distinct, traceable relationship with sunspots.
(2) Proper attention must be given to choice of vertical and horizontal scales used for plotting; otherwise, the cycles, whose amplitudes of swing may be very slight, will not easily be discernible.
(3) All rainfall graphs follow the same general pattern, even if they may differ materially in the limits of their departure from the mean value.
(4) After the phase of the trends of rainfall has been determined, with respect to the long swing curve in the sunspot numbers, a great similarity between the different rainfall graphs is observed. Rain-

fall all over the world is brought about by the same "causes", even though the lapse of time before the "effect" takes place, varies.

While the foregoing remarks have been applied to rainfall they may cover run-off data as well. In fact, run-off data give much better cycles, as the drainage areas act as integrators. The advantage of being able to identify these cycles is simply that they provide an index of the trends of the graphs, which is of value for bridging gaps in the past, and for indicating the probable times of future peaks or troughs, some years in advance. The extreme of rainfall, as listed in Table 1 (Appendix I), can now be used to greater advantage, especially if the year and month of their occurrence is noted.

If a hydrologist knows when to look for a peak in the Bruckner cycle in rainfall data at a certain locality, he has a good idea of the period of flood occurrence, referring to the great floods. Floods do occur at or near the troughs of the Bruckner curve, but they do not reach the magnitude of the others. Each section of the country needs to be studied individually. The times of flood occurrence can be marked on the Bruckner cycle in the rainfall graph, and note can be made of the position of such occurrence. It is believed that greater accuracy as to flood occurrence and magnitude can be secured by this type of study than by treating all flood data by means of frequency curves and probability methods.

A. Streiff, M. Am. Soc. C. E., has shown how to estimate the total run-off on a river for future years if twelve years of monthly means, determined by fairly good gauging, are available.[13] Considering also that most rivers lag behind the rainfall over their drainage areas from one to five months, it is quite obvious that hydrologists need no longer remain in the dark as to the total annual water output of the river for the next year. The extremes of discharge during the year, constituting floods, require much further study.

The fact of lag or lead in phase of the trends of rainfall, with the common great cause, explains why local floods occurred in Alabama in the autumn of 1929, while at the same time the region around Seattle, Wash., was suffering from one of its worst droughts. Each section of the country, part of a State, etc., is performing its cycle of operations, giving now wetter and now dryer weather, in accordance with these cycles. If the troughs or crests of the Bruckner and the Secular cycles happen to come close to phase, the extremes of rainfall occur. If the parts of the country which feed rivers that eventually come together (such as the drainage areas of the Mississippi River) happen to have cycle phases that practically coincide, then the great floods such as that in 1927, occur.

The graph of Greenwich, indicates a peak of the Bruckner cycle about 1929 (Fig. 8(*e*)). On January 7, 1928, one of London's worst storms occurred. The graph of New Orleans, La. (Fig. 8(*c*)), indicates a Bruckner cycle crest about 1926. On September 8, 1929, this city had a great storm, with 10.75 in. of rain falling in 24 hours.

It is conceivable, then, that the great floods of the Mississippi are the results of the phase coincidence of these important cycles. The writer suggests that the Mississippi River Commission make an analysis along the lines

[13] *Monthly Weather Review*, March, 1928.

outlined, studying each tributary river first, then combining the results for a grand total and a grand resulting series of cycles. Noting on these curves the flood times that have occurred in the past, the Commission should have much more data by which to predict future floods than it has by means of previous studies that have all been based on the theory of probability. Probability deals with numbers that occur purely by chance. It is the writer's opinion that rainfall and run-off data are not chance numbers, but are related to a great "cause".

CLINTON L. BOGERT,[14] M. AM. SOC. C. E. (by letter).—Only those who have put in tedious hours, days, and weeks in compiling, classifying, weighting, and averaging long-term rainfall and stream-flow records can really appreciate the immense amount of drudgery which the author has undergone in producing Table 1 (Appendix I). The profession should be deeply obligated to him for the form and extent of the results.

In this table the author has attained his desideratum of rigorous condensation, at a sacrifice of some essential data. The usability of the data in localities where stream-flow records are published, would have been increased materially were the year entered in the record when each minimum and maximum rainfall (both yearly and monthly) occurred. The dates would also be of value in investigations of droughts and amplitude of rainfall cycles.

In using any observed data, such as rainfall, there is one element of error which is often overlooked: All observers are assumed to make and record their observations with equal conscientiousness and accuracy. Of course, this is humanly impossible. The observations from which Table 1 (Appendix I) is made up, run into the millions, and to all, the same accuracy is assigned. The author's method of expressing results in percentages will reduce this error of observation and recording to some extent.

The value of Table 1 (Appendix I) for further research would have been enhanced had there been space available for assigning to each of the 820 stations a specific reference as to the source of the data.

R. W. POWELL,[15] ASSOC. M. AM. SOC. C. E. (by letter).—In making this complete compilation of rainfall data the author has rendered a great service to the Civil Engineering Profession, and his discussion of the data is also helpful. The writer wishes merely to comment on two or three of the many phases treated.

The author states that "no direct relation is treaceable between rainfall and sunspot periodicity", which seems to dismiss too lightly the results of the extensive study that has been put on this subject. The writer would not go as far as such extreme "cyclists" as Alter,[16] Streiff,[17] or Gillette,[18] but it seems

that there must be some truth behind their computations. The studies of men like Huntington[19] and Clayton[20] seem to establish a scientific basis for a relationship between solar radiation and rainfall.

Some studies on this subject have convinced the writer that the variations in annual rainfall do not take place purely at random but must be regarded as random variations of fairly large amplitude superimposed upon several cyclic variations of smaller amplitude. For example, the following equation was deduced for Boston, Mass.:[21]

$$y = 44.22 + 8.60 \cos \frac{k\,(x - 1767)}{96} + 2.58 \cos \frac{k\,(x - 1773)}{47}$$

$$+ 2.70 \cos \frac{k\,(x - 1798)}{34} + 2.56 \cos \frac{k\,(x - 1811)}{18} + 1.88 \cos \frac{k\,(x - 1810)}{10} \ldots (1)$$

in which, $y$ is inches of rainfall to be expected in any given year; $k$ is 360 to give the angle, in degrees, or $2\pi$ to give it, in radians; and $x$ is the date (A. D.) of the year considered.

The 111 years of record from 1818 to 1928, inclusive, fitted this equation with an average deviation of 4.28 in., while the average deviation from the mean was 6.36 in. Equation (1) is not recommended for use in forecasting the rainfall at Boston; it is given simply to illustrate the fact that after the best combination of cycles has been selected to fit any given set of data, the individual deviations will still be large. However, the cycles concealed by these random deviations may still be real, and the writer believes that one of them will usually have a period of about eleven years, and will synchronize with the variations in sunspots. Equation (1) is purely empirical; the denominator of the last fraction could have been changed to 11 or 11.2; some of the coefficients could have been changed slightly, and the equation would have fitted the data nearly as well.

The other point upon which the writer wishes to comment is variability or dispersion of the amounts of annual rainfall at a given station, when no account is taken of the order of occurrence. When the figures for annual rainfall are arranged in the order of magnitude, what is the result? The author has touched upon this question by presenting Fig. 3, which is a semi-logarithmic plotting of part of the data for four stations; but for the remainder he has indicated the variability only by giving the maximum and minimum of the observed values. This is manifestly a very uncertain method of describing the variability, because it depends on only the two measurements and neglects all the others; and also because it depends quite a little on the length of the period of record. As Fig. 3 shows, if 20 years of record have indicated a certain range between maximum and minimum, it is probable that 200 years of record at the same station will show a range of about twice as much. If the data for all the stations were plotted in this same way the lines for the stations

where the annual rainfall is most variable would be steepest and the slope, or some number depending upon it, could be taken as a measure of the variability.

In a paper entitled, "Flow in California Streams"[22] data are given for annual rainfall for about 260 California stations for the 50 water years, 1871-72 to 1920-21 (or for those of them that are known). Rainfall is expressed both in inches and in percentage of the average rainfall for those years. For a supplementary list of 17 stations the data are given in inches only; 41 of the stations in the first group are included in the author's list. To these, the writer added 4 from the supplementary table and for each of these 45, he plotted a graph. Figs. 9 and 10 are the plottings for Stockton, Folsom, and Sterling. These show the method and illustrate one of the less variable stations, one more nearly the average, and the most variable, respectively. The

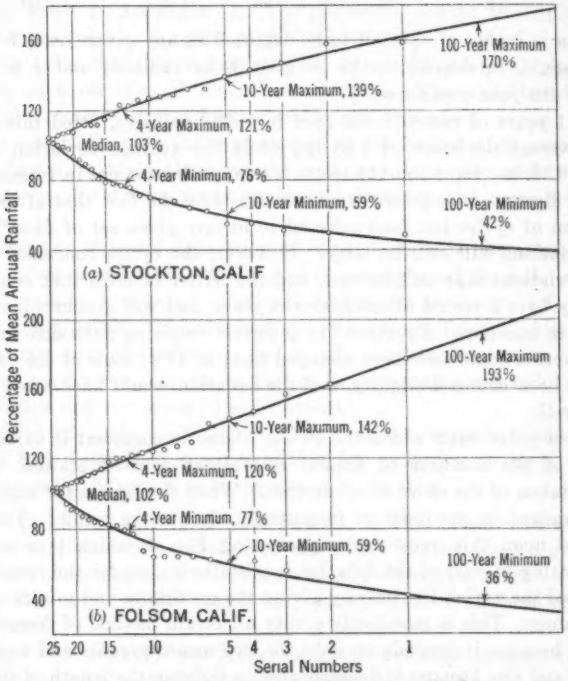

FIG. 9.—VARIATION IN ANNUAL RAINFALL AT STOCKTON AND FOLSOM, CALIF.; 50-YEAR RECORD.

method of plotting is slightly different from that adopted by the author. The curves are turned so that the numbers increase from right to left instead of left to right and the serial number of the order of magnitude is plotted instead of "average period between occurrences of a given amount." This gives the same curve as the author's method without the trouble of computing the average periods or of plotting fractional amounts.

[22] *Bulletin No. 5*, Dept. of Public Works, Div. of Eng. and Irrig., State of California.

From these curves the expected maxima and minima every 4, 10, and 100 years, and the median values, were read and tabulated in Table 6. The 4-year maxima and minima are the quartile points, such that one-half the values come between them, one-quarter above, and one-quarter below. If the variation were according to the "normal law of error", half the difference between the 4-year maxima and minima would be the "probable error" or the standard deviation multiplied by 0.6745. At first thought, this would seem the best constant by which to measure variability; but it was found that stations with about the same range between 4-year maxima and minima displayed very different ranges

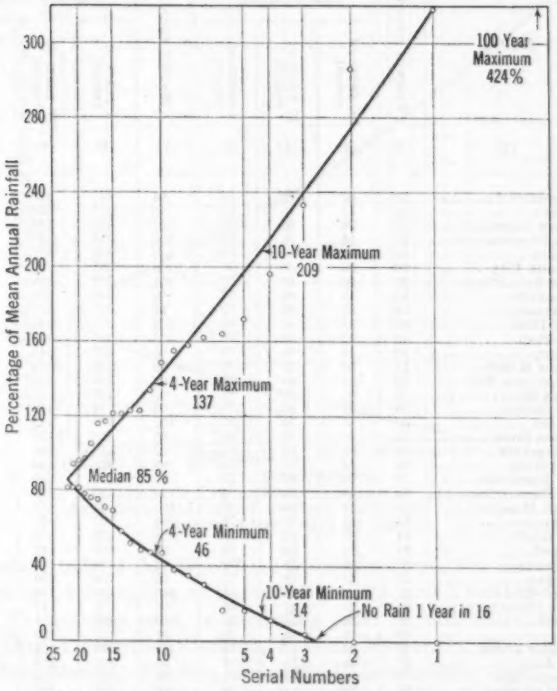

FIG. 10.—VARIATION IN ANNUAL RAINFALL AT STERLING, CALIF.; 45-YEAR RECORD.

between 100-year maxima and minima. However, as the period of record averages only about 40 years, the 100-year values are somewhat uncertain. It was thought best, therefore, to note the 10-year maxima and minima and to take their difference as a measure of the variability. This difference is tabulated in Column (11), Table 6, and the stations are arranged in the order of increasing variability as thus measured. Column (1) gives the number of the station corresponding to Column (1) of Table 1 (Appendix I). (It should be noted that the number of years of record is almost always less than that given

by the author, because the writer has generally included only data between the years 1871 and 1921). The values given in Table 6 are sufficient to enable one to reproduce the curve, so that the expected variation in any other period of years desired may be determined with an accuracy about as great as is justified by the original data.

† No rain 1 year in 16 years (on the average).

The curves given in Figs. 9 and 10 are typical and show that the line resulting from this semi-logarithmic plotting is not generally straight. Some investi-

gation was made of other methods of plotting. Hazen's arithmetic probability paper,[23] gives a line more curved than the semi-logarithmic. Hazen's logarithmic probability paper[24] is still worse. Goodrich's skew probability paper[25] was also tried and seemed about equal to Hazen's arithmetic paper. Hall's hydraulic probability paper[26] gave an almost straight line, as was to be expected since it was derived from the flow of California streams; but when data for the Northeastern United States and Northwestern Europe were plotted, it did not give as straight a line.

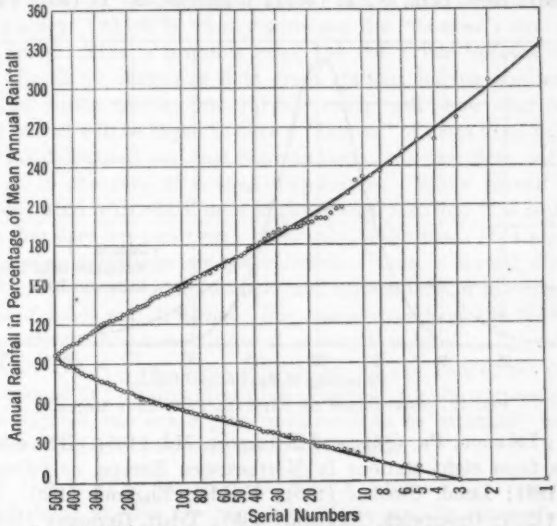

FIG. 11.—VARIATION IN ANNUAL RAINFALL AS ILLUSTRATED BY COMPOSITE DATA FROM TWENTY CALIFORNIA STATIONS, TOTALING 1 000 YEARS OF RECORD.

A further study of the slope of the frequency curves was made by using the composite data from twenty of the stations, which gave a total of 1 000 years of record. The stations used, in ascending order of variability, were Auburn, Nevada City, Placerville, Stockton, Folsom, Marysville, San Francisco, San Bernardino, Merced, Truckee, Bakersfield, Sacramento, San Luis Obispo, San Diego, Los Angeles, Santa Barbara, Independence, Indio, Mohave, and Sterling. It must be admitted that this selection is somewhat overweighted with stations of high variability and that the extreme values from a few stations appear very prominently, so that the resulting curve (Fig. 11), obtained by using these 1 000-year data as though they were all obtained at one station, is hardly typical of the State as a whole, but of its more variable

[26] "The Probable Variations in Yearly Run-Off as Determined from a Study of California Streams", by L. Standish Hall, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), pp. 191-257; Fig. 4, p. 211.

portion. In other words, the middle portion of the curve, excluding, say, the upper 50 and lower 50 of the 1 000 values, is fairly typical of the State as a whole, while the "tails" are typical of the most variable stations.

In Fig. 12, the frequency distribution of the California record is compared with that of two other series of composite rainfall records totaling 1 000 years of record each.[27] One consists of records from ten stations in the Northeastern United States, as follows (years of record given in parentheses); Boston (110); Lowell, Mass., (99); New Bedford, Mass. (108); Providence, R. I. (93); Albany, N. Y. (103); New York, N. Y. (103); Rochester, N. Y. (93); Philadelphia,

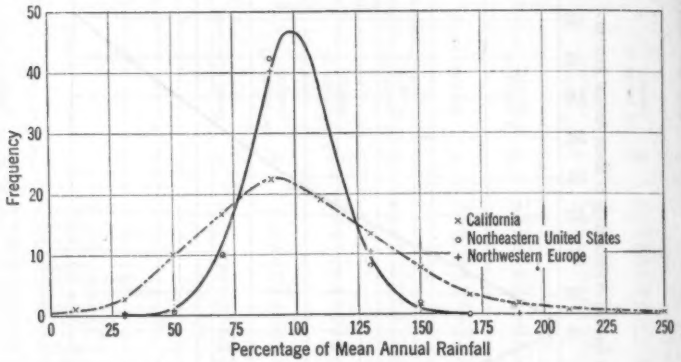

FIG. 12.—COMPARISON OF RAINFALL FREQUENCY RECORDS.

Pa. (103); Lebanon, Pa. (82); and Baltimore, Md. (106). The other consists of records from eight stations in Northeastern Europe, as follows: Paris, France (186); Lund, Sweden (160); Kendal, England (135); Edinburgh, Scotland (120); Greenwich, England (109); Tilsit, Germany (105); Copenhagen, Denmark (100); and Brussels, Belgium (85). The points for Northeastern United States and Northwestern Europe agreed so nearly that one curve was drawn to represent them both.

TABLE 7.—COMPARISON OF RAINFALL FREQUENCY RECORDS.

| Symbol. | Definition. | California stations. | Northeastern United States and Northwestern Europe. |
|---|---|---|---|
| $\sigma$ | Standard deviation, in percentage of annual rainfall. | 40.3 | 17.1 |
| $\sqrt{\beta_1}$ | Asymmetry, or skewness | 0.940 | 0.226 |
| $\beta_2$ | Flatness | 5.69 | 3.64 |
| $J$ | Type criterion | − 2.73 | − 1.13 |

These data were also investigated by the methods given by Fry.[28] Using his notation, the data gave the values listed in Table 7.

[27] From data in *Monthly Weather Review*, 1924, p. 485

[28] "Probability and Its Engineering Uses," Chapters VIII and IX.

These distributions (Table 7), therefore, can be represented by Pearson's Type IV, or by a Gram-Charlier series, or perhaps by some form not considered by Fry, such as that of Krichevsky.[29]

While no great importance can be attached to the values for California because the data are not really homogeneous enough to be combined, it is interesting to note that the California streams investigated by Hall[30] gave a "coefficient of variation" of 0.48, while the rainfall gives 0.403 (since the mean is 100% and "coefficient of variation" is defined as standard deviation ÷ mean).

H. R. Tolley states[31] that several hundred years of data are necessary before the fourth moment (which is what determines the "flatness") can be determined accurately. This is probably true, but the writer believes that it is allowable to build up composite data from stations having similar characteristics. The writer thinks that further study will show that ordinarily rainfall and run-off will be found to have a "flatness" of more than 3 (the value for "normal" distribution) and that extreme variations, therefore, will be more frequent than in the case of normal distribution. While normal distribution is the only kind with which most engineers are familiar, it is really a very special case that does not occur very commonly in Nature. If it proves to be true that extreme variations are more frequent than a normal distribution would call for, this fact may have important applications in investigating the probabilities of floods and droughts. For example, perhaps the 1894 flood on the Columbia River[32] was not so unusual as was thought.

The author's Fig. 4 is extremely interesting and one cannot but conjecture whether if, instead of "maximum rainfall observed" for the various periods at the various stations, one could plot "maximum to be expected" in, say, 10 years, one would not get even more consistent results.

GLEN N. COX,[33] JUN. AM. SOC. C. E. (by letter).—The results of the author's hydrologic studies are very valuable, especially since the rainfall records from all parts of the world have been studied and analyzed.

There is one consideration that should be kept in mind. With such an exhaustive study as this, the final results may not represent the facts in every detail. For example, in Fig. 13, the maximum rainfall of Iowa is shown as varying from more than 4 in. in the southeastern part to more than 7 in. in the northeastern and southwestern parts.

The values in Fig. 13 were taken from the Weather Bureau records published by the U. S. Department of Agriculture. These results show that an erroneous impression might be obtained from Fig. 5 as presented by the author. Bonaparte, Iowa, is in the southeastern part of the State, practically on the 5-in. isohyetal line in Fig. 5; yet the records show a measured rainfall of 12.10 in. from this station. Larrabee, with its 12.99 in. of measured rainfall, would be practically on a 6-in. isohyetal line. In Fig. 13 note the wide-

[33] Assoc. Prof., Dept. of Civ. Eng., Louisiana State Univ., Baton Rouge, La.

spread distribution of the stations which have had measured rainfalls in excess of 9 in.

It is quite evident that such a study as that presented by the author can only furnish general indications and that the records must be consulted for detailed information on the locality in question. It would sometimes prove

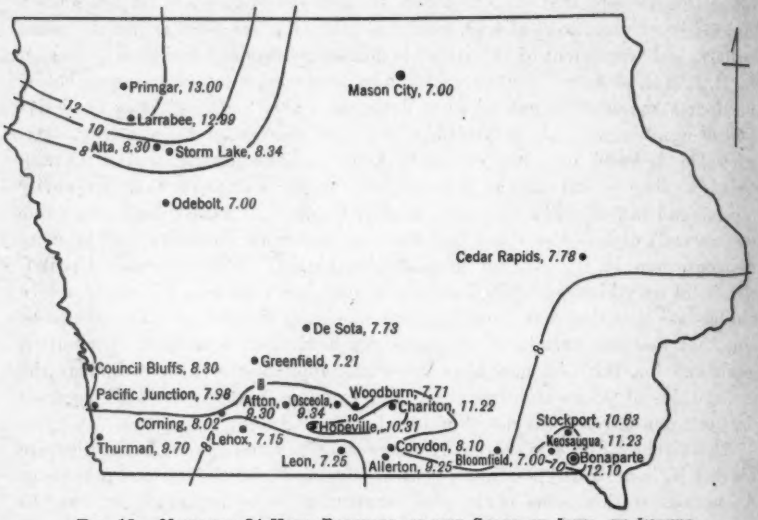

FIG. 13.—MAXIMUM 24-HOUR RAINFALL IN THE STATE OF IOWA, IN INCHES.

disastrous if engineering works were designed to handle such low values of rainfall as those shown in Fig. 5 for the State of Iowa.

C. R. PETTIS,[34] M. AM. SOC. C. E. (by letter).—Table 1 (Appendix I) is a distinct contribution to the subject of meteorology, and should be in the library of every engineer who is interested in the subject of river flood flow. It contains a great deal of information in convenient form, and from it an engineer can obtain some idea about the rainfall characteristics of almost every place in the world. The author has performed a difficult task, and he is to be congratulated on the result.

The comments made in this discussion are based on the relation of rainfall to river flood flow, and with particular reference to maximum precipitation and maximum floods. In most flood-control work hydrologists are mainly interested in the maximum quantity of rain to be expected in one storm. The book entitled, "Storm Rainfall of Eastern United States",[35] is an excellent study of storms in relation to their possible flood-producing qualities. In this report storm precipitation is considered for various periods of time, from one day to six days. In Table 1, the author gives precipitation data for one hour, one day, and one month; of these three periods the one-day precipitation gives the best indication of what may be expected in one storm.

[34] Lt. Col., Corps of Engrs., U. S. A., Fort Logan, Colo.
[35] Technical Rept., Pt. V, Miami Conservancy Dist.

In Table 1 (Appendix I), the flood-control engineer may use the 24-hour precipitation as an index, but he should keep in mind that the actual rainfall in one storm will generally be greater than the precipitation in 24 hours. Ordinarily, the one-storm rainfall will be greater than the one-day rainfall by about 50 per cent.

The 24-hour precipitation is the most valuable part of Table 1 for a flood-control engineer. The 24-hour data are missing for a large number of stations. For example, in Colorado, the values are given for only three out of fifteen stations. (See Items 281, 289, and 293.)

Table 8 gives the maximum observed precipitation, "day of 24 hours," for certain stations in Colorado, obtained from the U. S. Weather Bureau, and they may be used to fill in Table 1.

TABLE 8.—Observed Rainfall for Various Periods, in Colorado.

| Station No. | Station. | Maximum observed precipitation (day of 24 hours). | Station No. | Station. | Maximum observed precipitation (day of 24 hours). |
|---|---|---|---|---|---|
| 280 | Steamboat Springs | 2.7 | 287 | Longs Peak | 4.8 |
| 282 | Durango | 2.7 | 288 | Greeley | 3.4 |
| 283 | Wagon Wheel Gap | 2.6 | 289 | Denver | 6.5 |
| 284 | Gunnison | 1.6 | 291 | Lake Moraine | 5.5 |
| 285 | Marshall Pass | 1.5 | 292 | Colorado Springs | 4.3 |
| 286 | Leadville | 4.0 | 294 | Las Animas | 3.4 |

The author's discussion is interesting and instructive. It would appear that he might have made some more specific deductions after so much study; but the information is given in convenient form for a reader to make his own deductions.

The author has one paragraph entitled "Determinate Limits", in which he indicates that "it has long been recognized that there may be somewhat definite limits of rainfall intensity, frequency, duration, and variation applicable to given localities", and he adds that "an appreciation of the limited scope of human knowledge compared with the broad fields awaiting exploration deters the expression of opinions among those most competent to speak." In various other paragraphs the author evidently has the idea of "Determinate Limits" in mind. The writer wishes to express the opinion that for both practical and theoretical reasons it is much wiser to assume that there is no such thing as a determinate limit of rainfall intensity for any given locality. An effort will be made to reduce the question of determinate limits to concrete terms, and then some of the facts will be given upon which the writer has based his opinion.

According to a formula[36] introduced by the writer, the flood discharge of a stream varies directly with the precipitation in the storm that produces it, when the conditions are favorable for a heavy run-off, and when seepage can be practically neglected. In the United States, east of the Mississippi River seepage can be generally neglected if only the largest floods are being con-

[36] Meyer's "Elements of Hydrology," Second Edition, p. 378.

sidered. In the arid West seepage is more of a factor, but even there, in the larger storms, it seems to be almost negligible. In any case the relation between precipitation and run-off, or discharge, is such that if there is a determinate limit for the one there is a determinate limit for the other; and, similarly, if there is no determinate limit.

The relation between precipitation and run-off is further confirmed by a study[37] made by F. G. Switzer, Assoc. M. Am. Soc. C. E., and Mr. H. G. Miller.

The Foster method of applying the Pearsonian theory of probabilities, as described[38] by H. Alden Foster, Assoc. M. Am. Soc. C. E., has been adopted by a number of engineers. In using the Foster method for floods, the hydrologist must decide upon the type of curve to use for any particular set of observations. For all practical purposes the discussion may be limited to Type I and Type III. Type I has a definite upper limit, or determinate limit. Type III has no definite upper limit; or, in other words, the Type III probability curve is asymptotic to the $X$-axis, as is the case with the probability curve in the theory of least squares.

The question of determinate limits is thus closely related to the question of the relative merits of Type I and Type III curves. No engineer can design flood-control works with the meager data generally found in the United States, without basing his design on probabilities. The writer believes that the Foster method will come into wider use by engineers when its possibilities and limitations become better understood.

The question of determinate limits, whether decided one way or the other, will not have an unreasonable effect on engineering design. No matter what the long-time probabilities may be, there is always a determinate economic limit to the amount of money that may wisely be spent on an engineering project. It would not be wise to build levees to protect against a probable 1 000 000-year flood, any more than it would be wise to build houses in Kansas to protect against the worst tornado to be expected once in 1 000 000 years. It is essential that the engineer should have a definite conception of the degree of safety that he is attaining, and that there should be full value, for money spent, in safety, or other desirable features.

To illustrate the practical difference between determinate limits, and no determinate limits, attention is invited to the following figures which are taken from computations made for Bear River, Collinston, Utah:

| | Cubic feet per second. |
|---|---|
| Type I Curve; Determinate Limit: | |
| 10-year flood | 10 000 |
| 100-year flood | 12 000 |
| 10 000-year flood | 15 000 |
| Type III Curve; No Determinate Limit: | |
| 10-year flood | 10 000 |
| 100-year flood | 14 000 |
| 10 000-year flood | 22 000 |

[37] "Floods," by F. G. Switzer, Assoc. M. Am. Soc. C. E., and H. G. Miller, *Bulletin*, Eng. Experiment Station, Cornell Univ., Ithaca, N. Y.

[38] "Theoretical Frequency Curves and Their Application to Engineering Problems," by H. Alden Foster, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 142.

Attention is invited to the fact that for the Type I curve the 10 000-year flood is only 50% greater than the 10-year flood. This is a small spread, and would indicate that the river is very regular in its habits.

This illustration is given in order to help visualize the problem. If it is assumed that there is a determinate limit, this would imply a greater degree of regularity in the flood habits of rivers than seems reasonable to the writer. On the other hand, even if there is no determinate limit to rainfall or floods, there will still be a definite limit for economic engineering design.

If the Type III curve is adopted for the Bear River, it would still appear to be a reasonably steady stream, and quite satisfactory from the standpoint of engineering design. The writer has had occasion to use the Foster method with a number of streams of different sizes, and it is thought that the Bear River may be taken as fairly typical of probability characteristics.

The following is taken from the writer's notebook: The maximum flood on the Susquehanna River, at Williamsport, Pa., between 1895 and 1914, was 141 000 cu. ft. per sec. The 1889 flood was 350 000 cu. ft. per sec. Comparing this with the Bear River it could be assumed tentatively that the 1889 flood was about in the 10 000-year class.

The Juniata River, at Huntingdon, Pa., had a maximum discharge between 1896 and 1914 of 37 800 cu. ft. per sec. The 1889 flood was 106 000 cu. ft. per sec., which would seem to be considerably greater than the 10 000-year flood. The writer is of the opinion that neither one of the two 1889 floods was as unusual as indicated.

Another example: The maximum flood on the Arkansas River, at Pueblo, Colo., between 1895 and 1920, was 17 500 cu. ft. per sec. The maximum flood in 1894 was 39 100 cu. ft. per sec. The maximum flood in 1921 was 103 000 cu. ft. per sec. This would indicate that the Arkansas River in Colorado is not in the same class with the Bear River in the neighboring State of Utah. In 1920, the 1894 flood might have been considered near the limit. Then, how should the 1921 flood be classed?

Consider now some of the author's figures for rainfall. In Fig. 5 is represented the maximum 24-hour rainfall in the United States. In the Eastern and Central United States the isohyetals seem to be fairly well smoothed out so as to represent average conditions, except for one place in Southeastern Georgia, and another place in Texas. These two "humps" are undoubtedly due to two particular storms, and they not only stand out above anything in the vicinity, but above any other place in the United States. If the isohyetals in Texas surrounding the high spot are typical, then the one storm in Texas set a high determinate limit for one particular part of Texas. The 23-in. isohyetal is surrounded on three sides by the 8-in. isohyetal.

In Colorado, on the other hand, the isohyetals do not indicate anything out of the ordinary. In Table 1 (Appendix I), the author gives the maximum 1-day rainfall at Pueblo as 2.9 in., based on a 35-year record. According to his remarks on "Climatic Stability", a 35-year record may be considered to be fairly good. Nevertheless, there is evidence[39] that in 1921 there was a fall of about 12 in. of rain in 24 hours, within 6 miles of Pueblo. Furthermore,

[39] *Water Supply Paper* 487, U. S. Geological Survey, p. 13.

there is reason to suspect that in the same storm, in one or two small areas, there was an intensity of rain that might be compared to the Texas storm, which set the record for the United States.

Fig. 14 is based on the Weather Bureau records of 194 stations, in which the length of records varied from 5 years to 58 years. Isohyetals are based on the highest values of each group. The map is offered as a supplement to Fig. 5, and as illustrating the need for more detailed studies, especially where the topography is irregular.

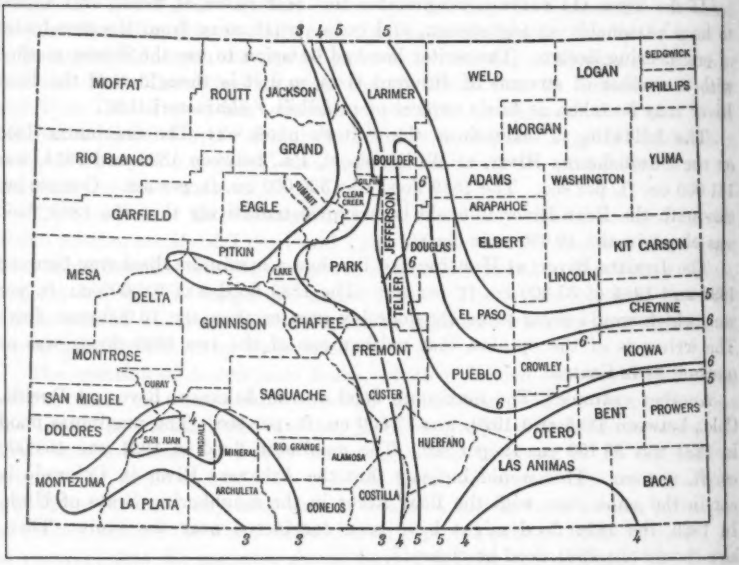

FIG. 14.—MAXIMUM 1-DAY RAINFALL, FOR COLORADO, IN INCHES.

"Cloudbursts" should be considered in any detailed study of Colorado weather conditions. It happens that none of the Colorado weather stations has experienced the most severe type of cloudburst, and this should be considered in using the isohyetal map. Largely on account of the topography, storm rainfall in Colorado is much more irregularly distributed than in the Eastern States.

There is need for further research and study along the lines of this discussion. In Mr. Foster's paper previously referred to, he states that "if in doubt as to which type curve to adopt, Type III may be selected as giving results on the safe side". The writer concurs. He would not adopt a Type I curve, "Determinate Limit," for any river with uncontrolled flow, unless he had sufficient evidence to controvert most of his previous experience along this line.

GEORGE C. DANFORTH,[40] M. AM. SOC. C. E. (by letter).—Among points which stand out in this paper are: The great value of the condensed data in

[40] Hydr. Engr., Augusta, Me.

Table 1 (Appendix I); a feeling that its value could be measurably increased by the inclusion of certain additional data; and the fact that uncertainties in connection with some of the place names bring out the importance of including the usual geographic co-ordinates for each station.

Incidentally, it seems desirable to express an appreciation of the value of "World Weather Records",[41] which is the source of the major part of the data listed in Table 1 (Appendix I). In this, stations are listed alphabetically by countries, and monthly and yearly values of precipitation, temperature, and pressure are given in the unit used in the original record. While there may be some question as to the advisability of abandoning the 10° squares of latitude and longitude of the Réseau Mondial, an index on that system is appended.

In Table 1 (Appendix I) the monthly precipitation is given for the "normal year", that is, the monthly means for the period of the record, and the stations are arranged in a novel and exceedingly useful form for the study of variations over large areas. While the table is valuable as it stands, it is felt that the engineer interested in run-off would greatly appreciate the inclusion of two additional "years" in the record, namely, monthly precipitation for an average year, and monthly precipitation for a minimum year.

In the United States the excellent data of the Geological Survey leaves little reason for attempting to derive a run-off from rainfall, but the greater part of the world has no available record of stream flow, and rainfall records must be used in preliminary estimates of available power. From this point of view it is felt that records for the average and minimum years are of greater importance than the record for the "normal year."

The importance of the minimum year record will be obvious. The need of figures for the average year (a year of the record the total of which equals or approximates the mean yearly total) is due to the fact that the "normal" year given in Table 1 (Appendix I) is fictitious; it probably never has occurred, and never will actually occur. The method of obtaining the "normal" year is one that smooths out the high spots. The fact that, in a given locality, six or eight months are dry, may not appear in its figures unless the dry months are the same year after year; this is rarely the case in fact. To illustrate the difference in the types of year under discussion, the monthly rainfall for two stations in Brazil is given in Table 9 for the "normal", average, and minimum year of the record. Alto da Serra is in the State of São Paulo, on the coastal side of the Serra do Mar, 2 625 ft. (800 m.) above sea level, latitude 23°47′S. It is in the path of the southeast trade winds, has a sub-tropical climate, and a high rainfall. Quixeramobim, in the State of Ceará, is in the interior of the dry northeast at an elevation of 679 ft. (207 m.), above sea level, latitude 5°16′ S. Its climate is tropical. These data are taken from "World Weather Records."

The stations in Table 1 (Appendix I) seem to be well chosen to give a general idea of climatic conditions. One exception to this may be noted in the case of Brazil.[42] No station is listed to indicate in any way the unusual condition prevailing in the so-called "sertão," the dry interior of the northeast. The coastal stations listed show a normal precipitation and the high rainfall of the Amazon Basin is near; nevertheless, the greater part of the States of

[41] Smithsonian Miscellaneous Collections, Vol. 79, 1927.

[42] Table 1 (Appendix I), Stations 375 to 380, inclusive.

Maranhão, Piauhy, Ceará, Rio Grande do Norte, Parahyba, Pernambuco, and Bahia have normally seven dry months or more a year, at which time the country assumes the aspect of a desert. At times, there have been 1-year or 2-year droughts, with heavy loss of life and cattle, and large emigration to other areas, notably during the "Great Drought" of 1877-79 in Ceará. The writer has had occasion to estimate the minimum flow on certain streams in Pernambuco. One appeared to have less than 1 cu. m. per sec. (35.3 sec-ft.) on an area of 2 980 sq. km. (1 852 sq. miles); and on 2 580 sq. km. (1 603 sq. miles) a minimum flow of zero. One station showing these conditions is listed in "World Weather Records", but was omitted from Table 1 (Appendix I). The area is amply covered in reports of the Directoria de Meteorologia de Brasil.

TABLE 9.—MEAN MONTHLY RAINFALL, IN INCHES,* OBSERVED AT TWO STATIONS IN BRAZIL.

| Month. | ALTO DA SERRA. | | | QUIXERAMOBIM. | | |
|---|---|---|---|---|---|---|
| | Normal. | Average. | Minimum. | Normal. | Average. | Minimum. |
| January | 16.6 | 15.4 | 7.0 | 3.1 | 0.8 | 4.7 |
| February | 15.4 | 20.1 | 10.3 | 3.5 | 5.1 | 0.3 |
| March | 14.4 | 10.4 | 14.8 | 5.7 | 8.4 | 1.9 |
| April | 12.1 | 13.0 | 10.4 | 4 8 | 4 3 | 0.6 |
| May | 8.4 | 10.5 | 1.1 | 3.7 | 2 6 | 0.6 |
| June | 7.7 | 7.2 | 0 | 1.5 | 2.1 | 0.2 |
| July | 6.7 | 5.3 | 7.0 | 0.8 | 1.3 | 1.3 |
| August | 7.8 | 13.9 | 5.1 | 0.4 | 0 | 0.7 |
| September | 10.7 | 7.0 | 2.5 | 0 08 | 0.1 | 0.08 |
| October | 12.4 | 13.7 | 5 4 | 0.04 | 0 | 0 |
| November | 14.1 | 14.1 | 8.6 | 0.2 | 0.3 | 0 |
| December | 14.8 | 11.0 | 17.0 | 1.1 | 0 | 0 |
| Total | 141.5 | 141.5 | 89.3 | 25.1 | 25.0 | 10.3 |

* Original data in millimeters.

While the addition of monthly temperature and pressure records might not have a value sufficient to balance the loss of compactness, it is felt that the mean annual temperature and pressure would be extremely useful. The temperature is of considerable interest to both the engineer and climatologist. The pressure is of interest in relation to the world belts of high and low pressure, such as the general high pressure (30.0 to 30.1 in.) of 30° latitude, falling off to 29.8° in the equatorial belt and toward either pole (29.9 at 60° N. and 29.3 at 60°S.)[43]

The value of a meteorological record depends much on ability to locate the station with reference to the coast line, mountain ranges, and prevailing winds. At many stations the exact location becomes of importance. For example, Alto da Serra (Station 376) in the State of São Paulo, Brazil, faces the sea near the top of the coastal range, intercepting rainfall from the prevalent southeast trades with resulting heavy precipitation, while the plateau, about six miles inland, is relatively dry.

[43] "World Weather," by H. H. Clayton, p. 29.

A casual examination of the remainder of Table 1 (Appendix I) shows that for some stations in Africa the country is given; for others, merely, "E. Africa", "W. Africa," etc. Certain stations in Java, Sumatra, and Timor are listed rather vaguely as "East Indies." The station listed as "Pará, near Belem, Brazil" is decidedly uncertain as to location. Belem is the city which has been called Pará erroneously on some English and American maps in the same way that Recife has been called Pernambuco, and Fortaleza has been called Ceará, using in each case the name of the State for its capital city. Belem is about 100 miles up the Amazon (this southern branch of the delta is actually the Rio Pará). There seems no way of determining from data at hand whether this station is 100 or more miles inland, or actually on the coast at Salinas, a third-class station listed by the Directoria de Meteorologia. In addition to a possible confusion resulting from errors or vagueness in place names, may be noted: (1) The possible duplication of names in the same country; (2) the fact that many towns and cities have changed their names (a common occurrence in South America); and (3) that many places have two names, one only appearing on this or that map. If the co-ordinates were given, these sources of uncertainty would be eliminated.

The statement is made that the greatest rainfall intensity occurs in subtropical and not in equatorial regions. While many of the stations in Table 1 (Appendix I) show no data on daily or hourly maximums, it appears to the writer that the high records are found rather generally in tropical areas. Table 1 (Appendix I) lists ten stations with a mean annual rainfall of more than 200 in. Of these, eight are tropical; the Formosa Station (494) is just inside or just outside the tropics (the name does not appear on available maps), with an elevation of 1 378 ft. The highest record listed is that of Cherrapunji (Station 515), in the Khasi Hills of Assam (Elevation 4 309). Its climate is sub-tropical (latitude 25° 16′ N.) and the mean rainfall given is 456 in., approximately one-half of which falls in June and July, and with a 24-hour precipitation of 40 in. (June 12, 1876). Similar conditions exist on the Western Ghats, a mountain barrier to the southwest monsoon, where precipitation increases with altitude to 250 in. at Mahabaleshwar, while the tableland of Deccan to the east is subject to drought. Baguio (Station 492), in Northern Luzon, with a yearly average of 182.0 in. and a daily maximum of 46.0 in. (July 15, 1911), and with an elevation of 4 959 ft. (latitude about 17° N.), is on a similar mountain barrier to the same monsoon. The wind is from the southeast, but both here and in India the movement during the northern summer is from the sea toward the heated land area of Southeastern Asia.

Of fourteen stations listed with a mean annual rainfall between 150 and 200 in., eleven are tropical and three are temperate, the latter with elevations between 1 100 and 4 400 ft. The highest record shown for North America and South America is that at Buenaventura, on the Choco Coast of Colombia (Station 346), with an average of 280.6 in. Mr. Leo Miller, of the American Museum of Natural History, is authority for the statement that the average rainfall on the San Juan River Basin just north of Buenaventura (latitude about 3° N.), is more than 400 in.

Of these twenty-five high records, twenty are definitely tropical, two are either tropical or slightly over the border, and all five exceptions have elevations between 1 000 and 4 400 ft. It seems probable, however, that the location of these high records in the tropics is due to the fact that monsoon or trade winds moving over a wide expanse of sea are commonly found in tropical areas. When these winds of high humidity meet a physical obstruction, such as the Serra do Mar in Brazil, the hill country in India, or the elevations in Hawaii in the path of the northeast trades, forcing moisture-laden air to cooler altitudes, heavy precipitation occurs, the opposite side of the obstruction being comparatively dry. The forcing of moisture-laden air to cooler altitudes with resulting precipitation may also be a result of atmospheric conditions, such as the meeting of southeast and northeast trade winds on the Lower Amazon.

In discussing altitude and precipitation A. J. Henry, Meteorologist, U. S. Weather Bureau, stated,[44] "The most favorable conditions for an increase in precipitation with increase in altitude, *viz.*, saturated air and relatively high temperature, are found in the tropics." The word, "tropics," in this case presumably refers to the area between 23° 27′ north and south latitude, which is the geographic definition, and the writer has used it with that meaning. From a climatic point of view, however, it seems reasonable to consider it as lying between the two high pressure belts at about 30°, which separate the trade wind areas from the west to east cyclonic movements of the temperate zones. While the equatorial rain belt oscillates roughly between 20° N. and 20° S., the 30° limit would include also the monsoon areas and all the high rainfall records except in the mountains of Wales.

*Evaporation.*—The evaporation data given in Table 2 are of some interest, together with the inference that they are given for use as indices of evaporation from a free water surface. This table shows for only a small percentage of the stations listed whether the record was from a land or a floating pan and in no instance is information given concerning the size of the pan and the conditions under which it was exposed.

Some confusion still exists (as a perusal of some recent textbooks will prove), concerning the relation between the actual evaporation from open water and that obtained from floating and land pans. Much valuable information on this subject is available in papers presented before the Society, particularly in the discussions on the paper by the late Edwin Duryea, Jr., and H. L. Haehl, Members, Am. Soc. C. E., entitled "A Study of the Depth of Annual Evaporation from Lake Conchos, Mexico,"[45] and in the paper on "Evaporation on United States Reclamation Projects," by Ivan E. Houk, M. Am. Soc. C. E.,[46] and the discussions thereon. The writer has reached the conclusion, from these data, and from his own experiments, that a floating pan properly installed and of such depth that the temperature of the water in the pan is the same as that in the reservoir, will approximate the evaporation from the reservoir. He has also reached the conclusion that the land pan is

[44] *Monthly Weather Review*, January, 1919, p. 34.
[45] *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1829, *et seq.*
[46] *Loc. cit.*, Vol. 90 (1927), p. 266.

useless without definite information as to its size and method of exposure, and that its records are of doubtful value unless a coefficient has been obtained by comparison with a properly installed floating pan at the same site. If monthly records are to be used, the coefficient must be obtained from monthly comparisons as it varies decidedly throughout the year.

C. S. JARVIS, M. AM. SOC. C. E. (by letter).—The generous response in the way of discussion and constructive criticism from members of the engineering and other scientific professions has brought forth essential items or phases of the subject which no single viewpoint could encompass.

In spite of earnest endeavors to condense data to the utmost limit compatible with reasonable use, the tabulation was regarded by some reviewers as entirely too voluminous for reproduction. It is evident from occasional comments within the discussions, and likewise freely admitted by the writer, that improvement might have resulted from extending the number of stations. The 820 meteorological records and subsequent interpolations listed in Table 1 (Appendix I) were selected from 10 000 or more consulted. In an effort to be consistent, the number of representative stations chosen from among highly developed and populous countries was stringently reduced from those available, while careful gleaning of all fragments of data was required in undeveloped regions, such as the deep interior of Africa, in order that any semblance of a comprehensive view could be provided.

The great danger of "deployment in a thin line to traverse a wide front" is that the individual responsibility is thereby increased, and the danger of wide gaps intensified. Continuing the analogy, the relatively few rainfall stations selected at wide intervals to represent groups in adjacent territory, failed in some instances to reflect the entire range of behavior or precipitation patterns. However, doubling or trebling the volume of data in Table 1 (Appendix I) would not have eliminated this inherent weakness entirely, due to sparsity of numbers, and would have rendered it somewhat unwieldy without commensurate returns in the quality of information.

Mr. Bliss evidently recognizes the preliminary steps leading up to the design and formulation of projects for flood control; namely, evaluation of rainfall intensities, duration, and intervals between probable recurrences. These, with other influences, are, after all, translated by natural phenomena into such stern realities as river gauge heights and corresponding velocities, discharge, and destructive dynamic effect.

Major Somervell points out the errors into which one might be led through neglect of the local station records. No method has yet been devised to supplant the use of all available data for a given problem. The comparatively long and complete record of Washington, D. C., so nearly identical with those of Baltimore, Md., and intervening stations, was chosen to represent the coastal plain section; while the Elkins, W. Va., meteorological data seemed to typify behavior of the mountainous region from which the head-waters of the Potomac and Monongahela Rivers flow. Neither was intended to represent an average value for the water-shed, nor an extreme of range. It is only by coincidence that the average annual rainfall determined by stream survey

investigations for the Potomac River Basin should agree so closely with the mean published for the National Capital.

It is not at all surprising that extremes of annual rainfall at other stations should go beyond the range of the Elkins and Washington records. Bayard, W. Va., at Elevation 2 700, and with annual mean of 53.99 in. for 22 years of record extending intermittently to include 1929, should normally record a correspondingly higher maximum than that for Washington in nearly the ratio of their respective means, 40.5 to 53.99 in., in a given period. By proportion, 40.5 : 53.99 : : 61.3 : 81.7, showing that the maximum of 89.01 in. recorded for Bayard during 1926 is not far beyond the normally expected range for a century.

The minimum of 12.71 in. for 1895 at Western Port, Md., is probably in error, as is made quite evident by a comparison with either the few near-by stations, or the several in the surrounding country listed in Table 10. Other circumstantial evidence against the reported rainfall during 1895 at Western Port accrues from the fact that this was the first full year of record, and was subject to the disadvantage of local inexperience regarding standard methods; the recurrence of four annual rainfall depths, next in order as minima during a 35-year record, ranging between 26 and 27 in.; and the surprising deficiencies, month by month throughout most of the year, as compared with the near-by stations of Cumberland, Boettcherville, and Burlington (six-month record only), which occupy comparable positions on the terrain, although at somewhat less elevation.

Whether the Western Port minimum annual precipitation of 12.71 in. is regarded as an error in observation, or only a local freak of a sub-normal rainfall, it cannot be regarded as representative over any considerable section of the Potomac River water-shed; it would be more consistent to base judgment on a group of meteorological stations, or selected ones which represent their average behavior.

The principal value of such summaries as comprise Table 1 (Appendix I) is in furnishing a background against which the detailed data of local stations may be more broadly interpreted. No claim has been made that such a summary will supplant local information; instead, it calls for all the information available, and assists in utilizing fragmentary data. A broad view of a field of research should precede the detailed study.

Mr. Shuman brings forth in attractive form the claims for periodicity of rainfall variations with relation to sunspot numbers. No one can doubt that series of years may differ in total precipitation; but the abrupt manner of changing from one extreme to another supports the impression that a portion of the normal rainfall that was temporarily withheld was later released; or a reserve somewhat depleted by unusual expenditures must await recuperation before resuming normal habits.

The comment from Mr. Shuman's discussion to the effect that, "if too large an area is taken, the data at one end or part of the district may neutralize those of another section, and one may secure no recognizable cycles," displays the weakness of the claims for sunspot influence. It reduces the coincidences to local happenings entirely, as the writer sees the problem. Ever

* With such consistent relations between the records at Western Port, Md., and neighboring stations, in all other years, it appears that the 1895 record is in error.

† At Burlington, January to June, 1895, total depth of 14.91 in.; no record for remainder of 1895; probably annual rainfall for entire year exceeded 28 in.

‡ First year of record; probably in error; rainfall for the year may have exceeded 20 in.

since reliable records were initiated, there have been areas of either excessive or deficient rainfall reported; and these again have years of above normal or below normal deliveries for their respective localities. The Eastern States suffered from drought during the summer of 1930 while various other sections of the country had unusually heavy precipitation, and floods in various parts of Europe were wreaking great destruction.

If an investigator has the right to bring station records into apparent agreement of phase by assigning lags of up to ten years, then it is freely admitted that the crests and troughs of rainfall graphs may be made to coincide, for occasional short sections, with the various cycles devised, while other stations are in opposition. Why not accept the conclusions promulgated by careful observers after diligent research—that sunspot increase was accompanied or followed by increase of precipitation on about one-third of the land surface, and by a decrease on nearly an equal area; while, for the remaining third of the earth's surface, no conclusive data were available. The presumption is that either claim may be proved or disproved by nearly one-half the data, which to the writer indicates that there is "no direct relation traceable between rainfall and sunspot periodicity." If such a relation exists, as a number of reputable scientists earnestly believe and seek to establish, it is either too elusive or too thoroughly masked by local influences for definite identification at this time.

Although the pluviographs in Fig. 2 depict the behavior of only nine widely separated stations, the preliminary studies included platting of more than one hundred of the longest records chosen from all over the earth's surface, and there were nearly as many oppositions as agreements among the crests and troughs, in comparison with sunspot numbers, whether the latter are platted inverted or above the base line and whether annual rainfall for consecutive years or the progressive two-year means for the entire periods are platted.

The profession is indebted to Mr. Shuman for the clear exposition of his views on periodicity.

Mr. Bogert has pointed out how the value of the tabulation might be increased by designation of the time of occurrence for maxima and minima, both yearly and monthly. Such information could be used to advantage; but obviously it calls for another tabulation containing such supplemental data. An attempt was made to record such dates in the original compilation; but the encumbrance entailed thereby seemed to outweigh any immediate advantage.

Professor Powell has contributed interesting and valuable views on the subject of periodicity, with reference to the recurrence of maxima or minima of a given order. The writer recognizes the alternation of sub-normal, medium, or excessive rainfall years, either singly or in groups, as they happen to occur. A season of excessive precipitation for one locality occurs simultaneously with droughts in other districts. It seems to be largely a question of routing; a large number of natural forces and elements jointly determine the path traversed by the atmospheric currents on which procurement, transportation, and delivery of moisture depend. To extend the analogy with other supply prob-

lems, the first few thousand feet of atmospheric strata above the surface of the globe, whether land or sea, high or low in either elevation or latitude, represent the loaded vehicles; the counter-currents at higher levels represent "the return of the empties", or the vehicles of reduced capacity.

The foregoing view is supported, if not established, by the physical data of Table 3, which shows that, with normal distribution or gradation of temperature with altitude, and the corresponding moisture capacity, the lower 5 000-ft. depth of atmospheric strata, if at saturation, contains considerably more moisture subject to precipitation than all the combined layers above. That relation holds, no matter whether the reckoning begins at sea level, or from mountains of any known height.

The forces which are accountable for tidal phenomena and ocean currents should extend a kindred influence on atmospheric movement. A tidal range of about 3 ft. occurs in mid-ocean; a range of 7 ft. is not unusual along extensive coast lines; more than twice this amount, occasionally quadruple, occurs under special conditions. Usual ocean tidal phenomena correspond to ordinary barometric pressure variations, measured by about ½ in. of mercury column at official meteorological stations, if due account is taken of the higher mobility of gases and the greater weight of water, that is, a 34-ft. column balancing the entire atmospheric pressure over an equal area at sea level.

For the extremes of observed readings, about 27.6 and 31.4 in. at the same datum, showing a total variation of more than 12%, the analogous ocean tidal range is 30 ft., or more, which may represent a considerably greater proportion of the effective offshore depth of water than the 12% range of barometric pressure noted in the foregoing remarks.

The alternation of high and low tides throughout the day seems to have its counterpart in atmospheric movements producing recurrent showers, such as those so often observed near noon or mid-afternoon, depending somewhat on latitude and the sun's declination. In desert regions, the increased convectional circulation during midday is readily traceable by the numerous whirlwind eddies, bearing aloft bits of leaves or other light substances, in a veil of dust, and displaying the main characteristics of cyclones in miniature, except that there is seldom attendant precipitation. When the desert heat has mounted under the blazing sunshine of successive cloudless days, and has approached the limit of human endurance, the most positive and pronounced relief may follow a violent thunder shower or dust storm. The first warning is likely to be a dust cloud on the far horizon, riven by lightning flashes; then a dull roar, increasing momentarily and punctuated by occasional thunder. In contrast, the prevailing calm and stillness are almost ominous until the moving curtain is within perhaps less than a mile of the observer, when he must suddenly combat fitful wind and cross-currents, followed by a murky cloud raised from the sweeping of the desert floor; then, infrequently, a brief deluge of rain, fiercely driven or occasionally interspersed with hail; and, finally, a few moments after the drenching, a cool, cleansed, and freshened atmosphere rapidly resumes the calm such as preceded the storm.

If the analogy continues to hold between atmospheric and ocean tides, there should be a fortnightly recurrence of unusually energetic circulation of

the atmosphere, corresponding to spring tides at seaports. Whether or not precipitation accompanies such disturbances, depends largely on relative humidity and the temperatures that prevail locally; in short, on the climatological habits. A systematic examination of prominent long-record meteorological data, day by day throughout any month or series of months, ordinarily discloses pronounced periods of maxima in wind movement, and, less frequently, in rainfall, occurring at fortnightly intervals or less. Secondary disturbances interspersed probably account for some of the occurrences.

From a consideration of evaporation rates from either free water surface, wet ground, or dense foliage, together with atmospheric moisture capacity, relief by condensation at intervals of a month or less may be regarded as unavoidable at some place along the path traversed, unless intermixed with air currents deficient in humidity. Whether the evaporation rate is the usual 4 in., or more, for months of moderate temperature, or less than 1 in. for a winter month in temperate zones, the corresponding moisture capacity of the entire atmospheric column would not be greatly in excess thereof for average prevailing temperatures. Under such conditions it appears that the initial steps in precipitation would begin at the nearest barrier, whether coast line, mountain range, or mass of dense, cold air obstructing the path of the warmer, moisture-laden currents.

After several hours of intense sunshine, without the moderating effect of free water for evaporation, the upward displacement of warm air to re-establish equilibrium doubtless produces an effect comparable with high tide in sea movements, and thereby affects rainfall distribution nearly as definitely as do the physical obstructions in mountainous regions.

A large number of cross-sections across mountain ranges discloses a fairly definite relation with respect to slopes. It appears that the abrupt changes in gradient also mark pronounced variations in rainfall. The top of the steepest slope, the highest point from which the entire lower slopes can be viewed (known in tactical problems as the military crest), seems to receive the greatest precipitation; and the actual summit may record a considerable reduction in amount. The leeward slopes with respect to moisture supply almost invariably receive deficient rainfall because of the increase of moisture capacity with temperature during the descent.

Professor Cox has pointed out such defects in the platting of isohyetals in Fig. 5 as must inevitably occur, in local sections, if only a few selected stations are utilized. On this account, General Note No. 3 of Fig. 7 is equally applicable to related Figs. 5 and 6, and was so intended, reading as follows: "This map is subject to revision by addition of data covering local variations not considered in Table 1".

It should be observed that the data from Table 1 (Appendix I), for Iowa stations, with one exception, terminated with 1920. Up to that time, the infrequent, sporadic occurrences of more than 7 in. in 24 hours, were so out of line with the usual habits that it appeared inadvisable to let those isolated data govern the platting in opposition to the general habits. Without exception such rainfall was the result of thunder showers during summer or adjacent

months and confined to restricted areas entirely away from the longest established and best equipped stations. Such problems demonstrate the importance of introducing the dimension or element of periodicity for interpreting and classifying observations of natural phenomena, as illustrated in Table 11 for annual rainfall.

From the new data contributed by the discussion, it appears that either an unusual number of intense 24-hour rainfalls have occurred in Iowa during the past decade, or else the list of stations must have been extended recently.

Mr. Danforth expresses an appreciation of "World Weather Records" in which the writer concurs, as far as the arrangement, convenience, and value of the data are concerned. This volume was published during the writer's quest for basic information, and includes 355 precipitation records, of which 251 were incorporated in Table 1 (Appendix I), in many instances supplemented by fragmentary data from other sources, or by extensions of summations so that the new means and extremes cover the entire period of available record.

The latitude and longitude co-ordinates were retained for purposes of identification of obscure or remote stations during the process of platting; but after the routing and the plotting of all stations on Fig. 7, the use of an entire line across two pages for such co-ordinates seemed to be out of proportion to the service that could be rendered thereby. Whenever the question of exact location enters into the problem, the length of record, the altitude of a station, and the rainfall patterns into which both the annual and the monthly means and extremes readily classify, should identify the particular station listed, even if there are others of the same designation, as in the case of two named Alto da Serra, in Brazil.

The use of such familiar names as Pernambuco and Para to indicate the principal ports of States bearing the same names, although technically incorrect, seems to be almost universal in news items, and extends to such standard volumes as "The Climate of the Continents",[47] by W. G. Kendrew.

Colonel Pettis has given evidence of broad experience and understanding concerning flood-flow phenomena and their relation to rainfall. The supplemental data for 24-hour periods at ten of the Colorado stations are gratefully acknowledged.

The question of determinate limits as used in the original paper was not intended to go beyond certain considerations, either axiomatic, logical, or demonstrable in the light of established facts. However, the discussion of typical curves derived from a study of probabilities is both interesting and instructive.

*Conclusions.*—For purposes of classification, it appears logical to compare rainfall distribution, either seasonal or annual, with normal evaporation from free water surfaces for the same periods. Where the potential losses from evaporation are approximately equal to the normal precipitation, the needs of ordinary crops on loamy or other fine-textured soils are abundantly supplied without recourse to artificial methods of application during average years.

[47] Oxford, Clarendon Press, 1922.

Where rainfall is habitually greatly in excess, the over-supply is manifested in the marshy character of both the soil and the vegetation, unless either surface or sub-soil drainage is unusually well developed. The regulating effect on run-off thereby produced is generally accentuated by the attendant habits of frequent gentle precipitation.

In contrast with the superabundant rainfall is the deficient rainfall, amounting to decidedly less than normal evaporation depths from free water surfaces, and ranging anywhere below, say, two-thirds of that amount. In a general way, the rainfall habits are recorded by both the surviving vegetation and the soil structures developed under varying degrees of aridity. The limits of plant rootage and moisture percolation, saturation, oxidation, leaching, and deposition are well marked by horizontal stratification and gradation of coloring, or by the widespread calcareous accretion in subsoil known as caliche or hardpan. The latter conserves to the utmost the sparse moisture supply, and hastens saturation or water-logging when it is supplemented by artificial means or by seasons of abnormally high rainfall.

With due regard to the foregoing definitions, the 15-in. average annual precipitation prevalent over extensive areas of Alaska, Canada, Greenland, Northern Europe, Siberia, and parts of the high Andes Mountain Range is comparable with approximately a 40-in. depth over the Middle Atlantic coastal plain, or with nearly double this rainfall in tropical lowlands; and, in each instance, the annual precipitation and evaporation should nearly balance. As progressive increase in altitude along a high mountain slope nearly reproduces the climatological and soil conditions of higher latitudes, the elevations above sea level for meteorological stations supply some of the primary factors in the study of rainfall and run-off; also, in the classification as to aridity or humidity of climate as determined by requirements for plant growth. For simplicity, the three principal classes previously defined may be regarded as those with deficient, moderate, or optimum (in technical terms for "ideal" or "most favorable" conditions), and, finally, excessive precipitation.

The temperate days and cool nights with heavy dew, so prevalent in the uplands as well as in high latitudes, reduce the demands for moisture measured as rainfall. This fact plus the advantage of strategic position, with priority privileges, so to speak, accorded to high mountain slopes, re-acts to make the uplands relatively immune to drought, while the lower interior valleys and plains are the first to suffer depletion, and the last to be served anew. High mountain peaks are swathed in fog, mist, or light rain, usually for hours both before and after the downpour that reaches the lowlands. The greater heights through which the droplets fall to reach the valleys afford opportunity for increased diameter of raindrops, velocity of descent, amount of electric potential induced thereby, further coalescence through attraction of opposite charges; and, finally, the lateral displacement of condensed moisture from its normal path of descent by cross-winds, producing an effect similar to the folding of curtain draperies, and resulting in multiplied intensity of rainfall in some parts of the storm area at the expense of depletion for others, located to windward.

| 797 | Helsingfors, Finland | 80 | 14 | 15 | 19 | 24.4 | 30 | 32 | 34 | 57 | 61 | 78 | 100 | 123 | 132 | 139 |
| 807 | Copenhagen, Denmark | 100 | 14 | 16 | 18 | 22.5 | 27 | 29 | 30 | 62 | 71 | 80 | 100 | 120 | 129 | 133 |

Such considerations account in part for the gentle, persistent rainfall of humid areas as opposed to the irregular, fitful, and violent phenomena of arid or semi-arid sections. In terms of stream flow or water supply, there is the discrimination between primary and secondary rights, with their contrasts of dependability. Whether the favored strategic position depends for its advantage on altitude, or on proximity to either the source of atmospheric moisture or its main lanes of traffic, or on the abrupt steepening of gradient to surmount a barrier, the beginnings of condensation merge almost imperceptibly with fog for part of the time.

If the wind movement becomes unusually strong, or if the energy released by the process of condensation is transformed into the kinetic phase to act as a propellant, then the storm may carry over the leeward side of the barrier, whether it is a land form, an underflowing mass of dense atmosphere, or merely the impediment of barren distance, for the relatively brief period of greatest activity and intensity.

The high ratios between successive values of either rainfall or percentage as given in Table 1 (Appendix I), are apparently a fair measure of relative aridity, whether the daily, monthly, or yearly periods are the basis of reckoning. For either moderate or excessive precipitation stations, either the depths of rainfall or the percentages of the mean annual which they represent (as tabulated), make fairly regular ascending series when read from left to right. For stations with deficient rainfall in comparison with potential evaporation from free water surfaces, the series is broken by occasional inversions or reversals. For example, the maximum monthly rainfall may far exceed the minimum annual, instead of being approximately one-half or two-thirds of the value in the next column, as seems to be characteristic of stations with dependable and ample rainfall. Furthermore, for stations of moderate rainfall, a typical 50-year record may show minimum and maximum percentages of about 50 and 150, respectively, or, more often, 60 and 140. For excessive rainfall stations, 70 and 130% may be more nearly representative, while for regions of marked deficiency of rainfall compared with potential evaporation, the range may be 40 and 200%, or, more rarely, nearly 30 and 300 per cent. Moreover, the average 10-year minima and maxima should ordinarily fall almost intermediate between the 100% and the foregoing extremes, although there may be lack of symmetry for some records, and decided departure from arithmetical series for others. The first approximations for 10-year minima and maxima for all the foregoing cases, and, in the same order, therefore, would be 75 and 125; 80 and 120; 85 and 115; 70 and 150; and, finally, 65 and 200%, respectively. Table 11 displays results of further studies along this line. Some of the irregularities may have resulted from varying reliability of either the rainfall data or the results of periodicity analysis.

As may reasonably be expected, the periodicity relations dealing with monthly rainfall display the same general trends and characteristics, but involve higher ratios. A fairly promising field awaits development along the same lines, but will require organized effort and facilities.

Synopsis

In providing for the growth of American cities, one of the major problems is that of maintaining an adequate and sanitary water supply. The rapid increase in population in Cleveland, Ohio, during the past two decades has necessitated a careful study of this particular problem. For more than fifteen years, the Engineering Division of the Department of Public Utilities has investigated, planned, and constructed means for providing an ample supply of pure water.

While the location of Cleveland on Lake Erie permits of an ample supply of water for the city proper as well as for a Metropolitan District involving about 500 sq. miles, the need for providing water of the proper quality had not received much consideration until about 1913. The City of Cleveland supplies water to about thirty-five political subdivisions of Cuyahoga County and to several communities outside that county. For the most part, these do not border upon the lake and, therefore, it has been necessary to consider the problem of water supply for Cleveland as one that in reality involved a Metropolitan District.

The object of this paper is to describe a part of the development of a comprehensive plan for supplying this district with pure water. Although

the City had constructed a filtration plant on the west side of the Cuyahoga River, which went into operation in 1918, only about one-half the supply was filtered until the Baldwin Plant was placed in operation in 1925. The water drawn through the City's intakes in Lake Erie is not as grossly polluted as many of the sources of public water supply of larger cities, but the growing population adjacent to the lake in this vicinity and the increased discharge of sewage directly into the lake have produced conditions that demanded an efficient purification system for the public water supply. This paper describes a large filtration plant into which has been introduced the most modern methods in the art of water purification and the largest covered concrete reservoir in the world. The paper has been subdivided as follows: History and Development of the Project; General Description of Flow of Water; Hydraulic Data; Design; Construction; General Equipment; Completion of Baldwin Filtration Plant; and Amount of Contracts and Analysis of Costs.

## History and Development of the Project

The southern portion of Lake Erie opposite the City of Cleveland is the source of supply for all water furnished by the municipality to the city proper, its suburbs and neighboring villages, as well as to the more distant parts of Cuyahoga County and a small part of Lake County to the east. Because this water is low in turbidity, averaging about 15 parts per million, no attempt was made until late in 1911 to treat the water furnished for consumption, in any way, except by chlorination. At that time, after a more or less prolonged controversy regarding the necessity of filtering the water supply, a decision was reached to start plans for a filtration plant. About the beginning of 1918, the Division Filtration Plant, on Division Avenue, between West 29th and West 53d Streets, with a capacity of 150 000 000 gal. per day, was placed in service, thus giving a section of the City of Cleveland its first supply of filtered water. In general, this plant was capable of supplying only that part of the city and vicinity lying west of about East 55th Street. The remainder of the area supplied continued to be furnished with chlorinated raw water only. However, before the Division Filtration Plant was completed, plans were under way for a new plant which, in conjunction with that at Division Avenue, would be capable of supplying the entire city and its principal suburbs with filtered water.

In line with the usual procedure of locating a filtration plant near the pumping station supplying it with raw water, the original plans for this plant contemplated its construction near the Kirtland Pumping Station, on the lake front, at the foot of East 49th Street. A study of this location, however, indicated that conditions were such as to require pile foundations for all structures. The area available on which a plant could be built was insufficient without a considerable fill being made in the lake, and this, in turn, necessitated the use of a more or less expensive coffer-dam type of

construction. Because of the difficulties to be overcome at the lake front site, the Engineers of the Cleveland Water Department gave consideration to the possibility of utilizing some other location.

It became evident about 1907, that the existing Fairmount Reservoir, supplying the low-service district, was becoming inadequate for storage purposes. It was also desired to increase the pressure in this service. Accordingly, during 1908 and 1909, the City purchased land for a new low-service distributing reservoir. This land was located directly east of Fairmount Reservoir and extended from Baldwin Road to East Boulevard. The new land was about 60 ft. higher than the surface of the water in the old reservoir, making possible increased pressures in the area to be served.

The possibility of utilizing the area in the vicinity of Baldwin Reservoir as another site for the new filtration plant was given serious thought. An estimate of cost revealed the fact that, with all factors taken into consideration, the Baldwin site was the cheaper. This finding was concurred in by an independent commission of engineers, composed of Messrs. J. W. Frazier, J. H. Herron, and Robert Hoffman, Members, Am. Soc. C. E., in a report dated June 1, 1920. As a result, the Baldwin Filtration Plant with a capacity of 165 000 000 gal. per day, was located on the Baldwin site, along the north, east, and south sides of Baldwin Reservoir. This location is approximately 3½ miles from Lake Erie.

The area within which the Baldwin Filtration Plant is located is approximately 50 acres. The filtration plant structures occupy approximately 11 acres and the Baldwin Reservoir about 13 acres. Fig. 1 shows the general location of the plant and the direction of flow of water.

The territory which the City of Cleveland will ultimately supply with water is a large metropolitan district destined to cover the entire area of Cuyahoga County and even to spread beyond its borders. The two existing filtration plants, having a total capacity of 315 000 000 gal. per day, will supply all needs until about 1930. By that time a third plant will be required in the eastern half of the county, and about ten years later a fourth in the western half.

## General Description of Flow of Water

The raw water for the Baldwin Filtration Plant is drawn from Lake Erie through a steel and concrete crib about 4 miles offshore, and thence through a 9-ft. brick-lined tunnel about 26 000 ft. long to the Kirtland Pumping Station. From there it is pumped through one lock-bar steel and three cast-iron raw-water mains, each 48 in. in diameter and about 7 500 ft. long. These four mains combine into two 60-in. lock-bar steel pipe lines, each approximately 15 000 ft. long, leading to Fairmount Reservoir. The water is then lifted by centrifugal pumps in Fairmount Pumping Station (see Fig. 1) and is forced through two 60-in. cast-iron mains, each approximately 2 100 ft. long, up the rising well in the chemical house of the filtration plant, to the upper pool of the three hydraulic-jump mixing flumes (capacity of each flume, 55 000 000 gal. per day).

Passing through these flumes (Fig. 1), the water flows through a channel approximately 124 ft. long, containing two pairs of under and over-baffles; and thence through Gate-House No. 1, into the south conduit of the coagulating basins. Here, it is distributed through two gate-houses into the four basins themselves. The water enters the coagulation basins at the south end over submerged weirs, travels through them, and leaves at the north end over similar weirs. The water then flows through the control gates and a conduit to the Administration Building, passing on its way through Gate-House No. 6.

The flow of water divides in the Administration Building, supplying the filters as shown in Fig. 1. From the filters, it passes through rate controllers into effluent galleries or small storage reservoirs. There is one gallery under each group of ten filters. The water flows from each of the galleries to a central conduit in the basement of the Administration Building, whence it divides and passes through sluice-gates into either one or both of the two basins of Baldwin Reservoir.

Water is delivered to these basins by means of multiple-weir flumes along the north side. It then passes across the basins and is collected on the south side at the bottom by means of openings in the conduits leading to Gate-House No. 7. There, the water is distributed by two 36-in. and three 48-in. mains into the low-service district of the city. Two other 48-in. mains leading from Gate-House No. 7, act as the suction mains for the first and second high-service pumps in Fairmount Pumping Station. The first high-service district is supplied from this station through two 30-in. mains and one 24-in. main; and the second high-service district, through one 30-in. main and one 48-in. main.

## Hydraulic Data

In the raw-water mains under full plant capacity, the computed velocity in the 48-in. mains is 3.3 ft. per sec., and in the 60-in. mains, 4.2 ft. per sec. With normal operating levels in the coagulation basins, the computed velocity in the channel leading from the hydraulic-jump mixing flumes to Gate-House No. 1, varies from 0.76 ft. to 1.20 ft. per sec., except at the under and over-baffles where a velocity of 2.53 ft. per sec. is reached. In the influent conduit of the coagulation basins, the computed velocity of the water is 2.17 ft. per sec. and in the effluent conduit, 2.42 ft. per sec., the latter being also approximately the maximum velocity through any of the sluice-gates. The flow through the coagulation basins is at a computed rate of 2.36 ft. per min. The computed velocity through the settled-water conduits is 2.37 ft. per sec., and through the settled-water piping leading to the filters, 2.04 ft. per sec.

It will be noted that the computed velocities of flow through conduits, sluice-gates, etc., after the water has passed through the hydraulic jumps, is less than 2½ ft. per sec. This is the value above which it was not desired to go on account of the possibility of breaking up the floc; but this velocity is exceeded if the coagulation basins are by-passed.

The computed loss of head through the filter plant, together with the actual losses obtained as the result of a series of observations made when the plant was operating at the nominal rated capacity of 165 000 000 gal. per day with

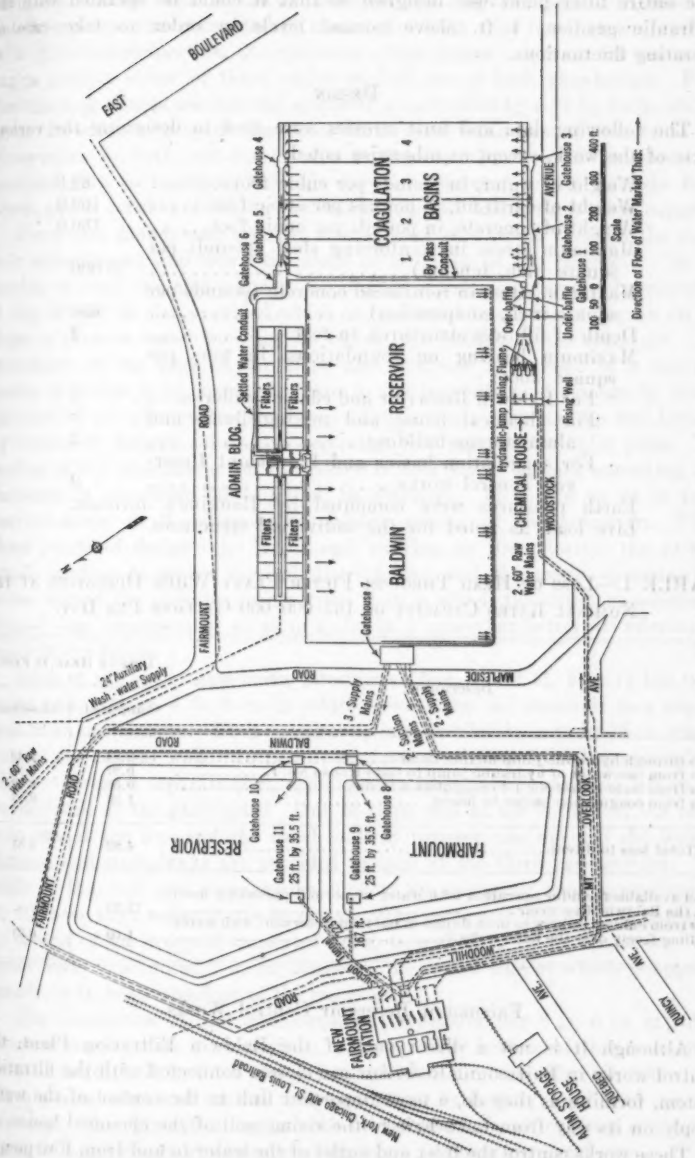

FIG. 1.—GENERAL ARRANGEMENT OF STRUCTURES AND DIRECTION OF FLOW OF WATER.

water at normal operating level in the coagulation basin, is shown in Table 1. The entire filter plant was designed so that it could be operated with the hydraulic gradient 1 ft. above normal levels in order to take care of operating fluctuations.

## Design

The following data and unit stresses were used in designing the various parts of the work, except as otherwise noted:

| | |
|---|---|
| Weight of water, in pounds per cubic foot | 62.5 |
| Weight of earth-fill, in pounds per cubic foot | 100.0 |
| Weight of concrete, in pounds per cubic foot | 150.0 |
| Maximum stress in reinforcing steel (pounds per square inch, tension) | 16 000 |
| Maximum stress in reinforced concrete (pounds per square inch, compression) | 650 |
| Depth of fill over structures, in feet | 2 |
| Maximum bearing on foundations, in tons per square foot: | |
| For Baldwin Reservoir and effluent galleries | 5 |
| For chemical house and mixing flume and alum storage building | 3 |
| For coagulation basins and Fairmount Reservoir control works | 2 |

Earth pressures were computed by Rankine's formula.
Live load, as noted for the individual structures.

TABLE 1.—Loss of Head Through Filter Plant When Operating at the Nominal Rated Capacity of 165 000 000 Gallons Per Day.

| Description. | Loss of Head, in Feet. | |
|---|---|---|
| | Computed. | Observed. |
| Loss through hydraulic-jump mixing flumes | 2.04 | 2.40 |
| Loss from tail-water of hydraulic jump to Gate-House No. 1 | 0.97 | 0.88 |
| Loss from Gate-House No. 1 to coagulation basins | 0.56 | 0.30 |
| Loss from coagulation basins to filters | 1.25 | 0.93 |
| Total loss to filters | 4.82 | 4.51 |
| Head available for filter operation with water at normal operating level in the Baldwin Reservoir | 11.75 | .... |
| Loss from effluent gallery to inlet flumes in Baldwin Reservoir, with water falling freely over the fixed weirs | 1.00 | 0.81 |

## Fairmount Reservoir Control Works

Although it is not a direct part of the Baldwin Filtration Plant, the control works in Fairmount Reservoir are closely connected with the filtration system, forming as they do, a most important link in the control of the water supply on its way from Lake Erie to the rising well of the chemical house.

These works control the inlet and outlet of the water to and from Fairmount Reservoir (see Fig. 1). As may be noted, each of the 60-in. raw-water mains

leads to a single inlet gate-house (No. 8 or No. 10) and each gate-house, in turn, is connected to one of the two basins comprising the reservoir. These two gate-houses are cross-connected by means of a 60-in. pipe line. In conjunction with this cross-connection, the operation of the proper valves on the raw-water mains permits either of these mains to feed one or both gate-houses. Flow through each gate-house into the reservoir is controlled by a 72 by 84-in. sluice-gate. In order to prevent the water from overflowing into the street, if the sluice-gates in both gate-houses are improperly closed, each gate-house is provided with an overflow, which is directly connected to the Baldwin Road sewer, and is capable of taking the flow of one-half of the filter plant capacity.

From each gate-house, a 72-in., riveted steel pipe passes through the reservoir embankment and down the slope to the floor of the reservoir. In the section through the embankment the pipe is entirely surrounded by concrete. A cut-off wall is also provided which is connected to a concrete apron on the slope to prevent water working its way to the outside of the reservoir. The remainder of the pipe on the slope and reservoir floor rests in a concrete cradle to which it is anchored. Due to the possibility of damage by ice to the part of the pipe on the slope, provision is made near the top and bottom, by means of flanged joints, for replacing this part of the inlet pipe. The section of the pipe laying on the reservoir floor slopes upward somewhat and increases in size from 72 to 96 in. in diameter. It is laid so as to point approximately to the diagonally opposite corner of the reservoir. These three points of design—the larger end, slowing up the velocity; the upward trend, tending to widen vertical distribution; and the angle, directing the water toward the opposite corner from that in which the outlet gate-house is located—are incorporated so as to assist in a somewhat better distribution of water in the basins.

Each of the outlet gate-house structures (Nos. 9 and 11, Fig. 1) has three water passageways, 4 ft. 8 in. in width, connecting the reservoir to a central well 12 ft. in diameter. Each passageway is controlled by a 42 by 72-in. sluice-gate at the central well. To permit water to be drawn from the reservoir at different levels, a separate port, opening into each passageway, was left in the outside wall of the gate-house. One of these was at the bottom of the reservoir, one at the top, and the third midway between the top and the bottom. Screens and stop-planks are provided in each of the three passageways. The walls of the well and passageways support an operating floor approximately 5½ ft. above high water in the reservoir. The bottom of the well is connected, by means of an inverted truncated cone, to a shaft 7 ft. in diameter. This latter leads to a tunnel 7 ft. in diameter, the center line of which is approximately 28 ft. below the floor of the reservoir.

The foundation of each gate-house has approximately 6 ft. 6 in. of rubble concrete topped with 2 ft. of plain concrete. The bottom of this foundation rests on hard shale and the top is just a little above the reservoir floor. The three passageways and central well are formed by heavily reinforced concrete sections. As a protection against ice in the reservoir, all exterior concrete is faced with granite to a point approximately 5 ft. below the overflow.

The tunnels (Fig. 1) leading from the outlet gate-house shafts converge and form one tunnel of the same diameter at a wye-intersection. Continuing

from this wye, the tunnel extends a distance of approximately 129 ft., where it joins a 7-ft. circular conduit, leading to the header on the suction of the low-lift pumps in Fairmount Pumping Station. The junction between each of the two vertical shafts and the tunnels is made with long-sweep radii in order to reduce loss of head.

The tunnel is bored through shale. Its cross-section is, in general, circular with a minimum thickness of shell of 12 in. At the approach to the wye, the section is made elliptical, 5 ft. 6 in. by 9 ft., with the long diameter vertical, in order to reduce to a minimum the width of unsupported roof at the wye proper. Except at the wye, where the roof becomes flat, the tunnel is composed of plain concrete. At the wye, §-in. square steel reinforcing hoops were placed on 4-in. centers. Provisions were also made in the shafts and tunnel for bulkheading in case it were necessary to use compressed air.

## Chemical House and Mixing Flumes

*General Description.*—The arrangement of the chemical house, mixing flumes, and channel is shown in Fig. 2. With the exception of the upper story of the chemical house, all the structures are of reinforced concrete of the beam-and-slab type with independent column footings. The upper story consists of brick bearing walls with steel roof trusses. The remainder of the building proper is of the skeleton type with brick curtain-walls. Basic data concerning this unit (see Fig. 2) may be listed, as follows:

| | |
|---|---|
| Nominal capacity of the plant, in million gallons daily | 165 |
| Elevation of water surface in the rising well | 245.74 |
| Concerning a point in the channel just before the hydraulic jump: | |
| Depth of water, in feet | 0.47 |
| Width of three flumes, in feet (each flume) | 14.56 |
| Velocity of water, in feet per second | 12.5 |
| Elevation of water surface | 242.82 |
| Concerning a point at the foot of the slope in the mixing chambers; nominal operating conditions: | |
| Depth of water, in feet | 3.19 |
| Width of water passages, in feet (three each at 22 ft.) | 66 |
| Velocity of water, in feet per second | 1.13 |
| Elevation of water surface | 243.69 |
| Loss of head, in feet, between the rising well and the foot of slope in the mixing chamber | 2.05 |
| Loss of head, in feet, between the foot of slope in the mixing chambers and the coagulation basins | 1.69 |
| Distance, in feet, down stream from the top of slope in the mixing chambers, to the location of the hydraulic jump | 8 |
| Flow-line elevation in the coagulation basins | 242.00 |
| Alum Storage Bins: | |
| Gross capacity, in tons | 450 |
| Net capacity, in tons | 350 |
| Dissolving Tanks: | |
| Volume, in cubic feet per tank, to the top of overflow plank weir | 157 |
| Charge of alum required, in pounds per tank | 4 000 |
| Solution Tanks: | |
| Capacity of each tank, in gallons | 9 600 |
| Alum, in 5% solution, required for each tank (tons) | 2 |
| Depth, in feet, of the solution in the tanks (for 9 600 gal.) | 4.62 |

| | |
|---|---|
| Summary of Alum Required: | |
| Maximum volume of water treated, in million gallons daily | 165 |
| Alum, in grains per gallon | 1 |
| Rate, in tons per day, in which alum is applied | 11.8 |
| Speed of bucket hoist, in feet per minute (capacity, 3 000 lb.) | 20 |
| Speed of passenger elevator, in feet per minute (capacity, 2 500 lb.) | 150 |
| Alum storage capacity, in tons, required to treat 165 000 000 gal. daily with 1 grain per gallon: | |
| Baldwin Chemical House (30-day supply) | 350 |
| Alum Storage Building (85-day supply) | 1 000 |
| Baldwin Chemical House, on the dissolving-tank floor (20-day supply) | 225 |
| Total storage capacity (135-day supply), approximately | 1 575 |
| Height, in feet, to which bags of chemicals may be stored | 3 |

*Chemical Bin Structures.*—The chemical bins (Fig. 2) occupy the major portion of the structure to the west of the rising well. They consist of two separate bins with a passageway between them, and with the top of the bins situated at the general ground level. This total net capacity is about 350 tons. The westerly bin extends the full width of the building, and the easterly one, a little less than one-half this distance. They are continuous, with seven hoppers in the large bin and three in the small one. The minimum side slope is approximately 45 degrees. The bins discharge through 12 by 14-in. steel chutes equipped with single undercut gates, operated with a chain-and-link mechanism. These chutes discharge into a bucket on a small industrial or transfer car that is spotted in a common passageway beneath the bins. The cover over the alum bins forms the floor of the receiving room (see Section *D-D*, Fig. 2). In this floor there is one manhole to approximately 90 sq. ft. of horizontal bin surface.

*Chemical Tanks and Piping.*—On the upper floor of the chemical house are located the tops of six dissolving and four solution tanks. These are divided evenly into two independent groups, each of which is connected with a double orifice box unit. The arrangement is such that the central dissolving tank in each group is capable of feeding either solution tank. A system of piping conveys the solution from the solution tanks to the orifice boxes and from there to the lead-lined distributing trough immediately over the rising well. Piping is also provided to convey the solution to a point of secondary application in Gate-House No. 6 which is in the outlet conduit from the coagulation basins.

All chemical piping is flanged cast iron and all valves are of acid bronze. In all cases in which this piping is joined to chemical tanks, special wall castings, no parts of which come in contact with the chemical solution, were provided. This will permit complete replacement of the chemical lines at any future time and at a minimum expenditure.

*Hydraulic-Jump Section.*—The raw water is introduced to the mixing-flume section, at its westerly end (see Fig. 2), by means of a rising well which extends entirely across the width of the chemical house. The raw water enters the rising well from two 60-in. mains.

Flowing from the upper pool, the water passes through three hydraulic-jump mixing flumes. These flumes have expanding sides and sloping bottoms, and are preceded by horizontal throats of constant width with curved entrances.

At the foot of the slopes, they lead into a converging horizontal flume (see Fig. 2). Provisions have been made in each throat for a double row of stop-planks in order to cut off the flow of water through the flume, if desired. The flumes are housed within a one-story building; walk-ways, conveniently located, permit an adequate view of the hydraulic jumps.

Just beyond the weir planks for controlling the tail-water depth, the converging shallow flume is transformed to a conduit section (see Fig. 2). This is accomplished by dropping the floor about 9 ft. and narrowing the sides, thus producing a conduit section about 19 ft. wide and 13 ft. deep leading to Gate-House No. 1. This conduit section, which is about 90 ft. long, has a pair of under and over-baffles near each end.

In order to present a more pleasing external appearance, the exterior walls of the chemical house were extended through to Gate-House No. 1, and the area between these walls and the conduit was roofed over at the level of the top of the conduit. Over this entire area an earth-fill, 2 ft. deep, was provided.

Parts of the space between the conduit and the exterior walls were utilized for garage, tool-room, and covered passageway. This passageway is part of a complete system, leading from the chemical house, along the coagulation basins, to the filter building. Beneath it is a tunnel in which are located the steam and water lines, secondary chemical feed pipes, and conduits for light, power, and telephone cables.

*Basis of Design.*—Except in the case of water passages, where maximum water heights are used, the usual live load is 75 lb. per sq. ft. On the floor where the dissolving tanks are located—owing to the possibility of storing sack alum—a live load of 250 lb. per sq. ft. is used. The floor over the alum storage bins is designed to carry a motor truck which, when loaded, weighs about 7 tons.

Expansion joints, extending down through the foundation, are provided at six places in the chemical house and mixing flumes. They are placed where pronounced changes are made in the general type of the structure, and, in addition, at one or two other places, so that in no case is there a distance between joints greater than 82 ft. The shape and proportions of the hydraulic-jump flumes, as well as the dissolving and solution[5] tanks, are based on experiments conducted by the Engineers of the Cleveland Water Department.[6]

## Coagulation Basins

The coagulation basins shown in Fig. 1, extend for a distance of nearly 500 ft. from the east wall of Baldwin Reservoir. Data pertaining to these basins are, as follows:

| | |
|---|---|
| Over-all area, in square feet, including conduits and gate-houses (457 ft. by 747 ft.) | 341 379 |

[5] "Rate of Solution of Sulphate of Alumina," by J. W. Ellms, A. G. Levy, and L. A. Marshall, *Journal*, Am. Water Works Assoc., July, 1921.

[6] "The Hydraulic Jump as a Mixing Device," by A. G. Levy and J. W. Ellms, *Journal*, Am. Water Works Assoc., January, 1927.

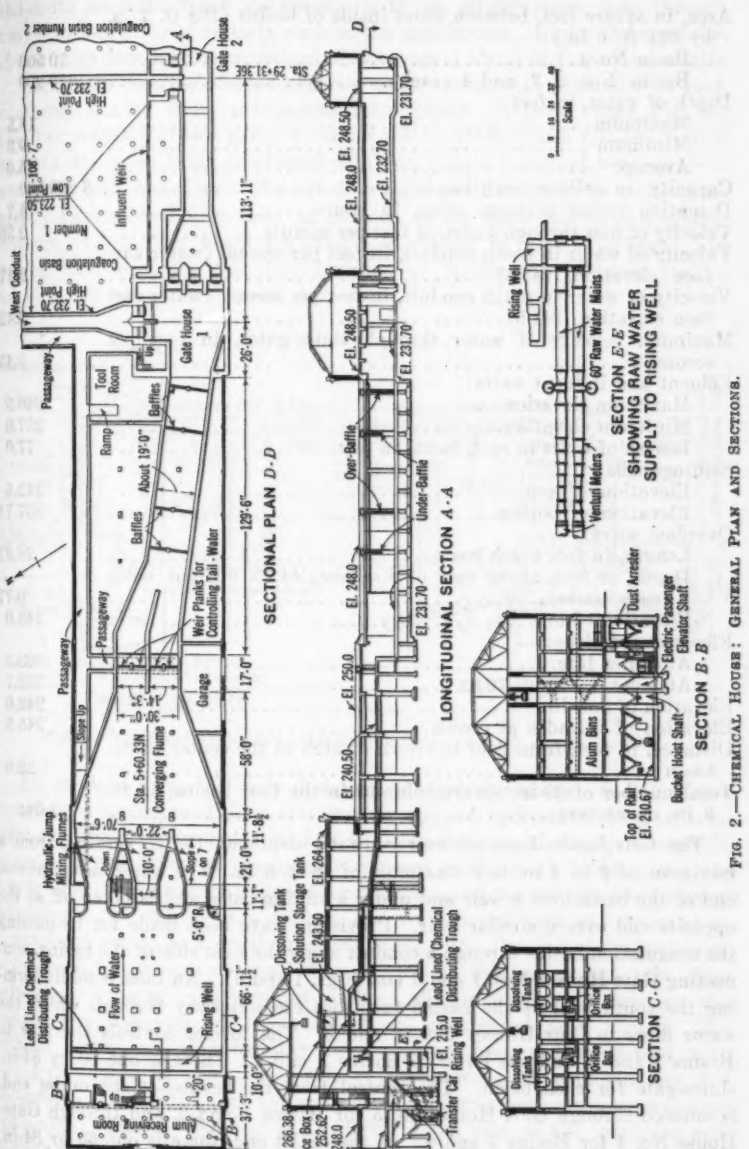

FIG. 2.—CHEMICAL HOUSE: GENERAL PLAN AND SECTIONS.

| | |
|---|---|
| Area, in square feet, between weirs inside of basins (108 ft. 7 in. by 661 ft. 6 in.): | |
| Basin No. 1 | 70 500 |
| Basins Nos. 2, 3, and 4 (each) | 70 900 |
| Depth of water, in feet: | |
| Maximum | 18.5 |
| Minimum | 9.3 |
| Average | 15.0 |
| Capacity, in gallons, each basin | 8 200 000 |
| Detention period between weirs, in hours | 4.7 |
| Velocity of flow through basin, in feet per minute | 2.36 |
| Velocity of water in south conduit, in feet per second (water surface elevation, 242.5) | 2.17 |
| Velocity of water in north conduit, in feet per second (water surface elevation, 241.5) | 2.42 |
| Maximum velocity of water through sluice-gates, in feet per second | 2.43 |
| Effluent and influent weirs: | |
| Maximum elevation | 240.5 |
| Minimum elevation | 237.0 |
| Length of weirs in each basin, in feet | 77.0 |
| Stilling-baffle: | |
| Elevation of top | 242.5 |
| Elevation of bottom | 237.71 |
| Overflow weirs: | |
| Length, in feet (each basin) | 28.27 |
| Depth, in feet, above weir to discharge 41 250 000 gal. daily (each basin) | 0.77 |
| Elevation of top | 243.0 |
| Elevation of floor: | |
| At center line | 223.5 |
| At sides | 232.7 |
| Elevation of flow line | 242.0 |
| Elevation of intrados at crown | 245.5 |
| Distance, in feet, from floor to crown of arch at the center of the basin | 22.0 |
| Total number of 20-in. square columns in the four basins, 15 ft. 9 in. on centers | 1 041 |

The four basins have an average water depth of 15 ft., varying from a minimum of 9 ft. 4 in. to a maximum of 18 ft. 6 in. The water enters at one end of the basin over a weir and under a stilling-baffle and is taken off at the opposite end over a similar weir. Provisions have been made for by-passing the coagulation basins through a conduit along the west side of the basins, connecting Gate-Houses Nos. 1 and 6 (see Figs. 1 and 3). An inlet conduit forming the south wall of the basins furnishes the waterway through which the water flows to Gate-Houses Nos. 2 and 3. The former controls the flow to Basins 1 and 2, and the latter to Basins 3 and 4. There is one 60 by 84-in. sluice-gate for each basin. The control from the basins, at the outlet end, is effected through Gate-House No. 5 for Basins 1 and 2, and through Gate-House No. 4 for Basins 3 and 4. At the outlet end, there is one 60 by 84-in. sluice-gate for each basin.

The by-pass control of the coagulation basins is effected through Gate-Houses Nos. 1 and 6, where the water may be shut off entirely from the north

and south conduits. When the by-pass is in use all the water flows through two 60 by 84-in. sluice-gates in each of the gate-houses. Under the condition of maximum flow, a velocity through these gates of about 3¾ ft. per sec. results.

Each basin is of reinforced concrete construction with groined arch roof, reinforced sloping floor, and independent column footings. (See Fig. 4.) The floor consists of two parts, a sub-floor 4 in. thick and a finished floor 8 in. thick, the latter being reinforced with ½-in. square deformed bars on 15-in. centers in both directions. The sub-floor butts against the walls and column bases. The finished floor rests on a ledge at the walls and at the column footings, and all floor joints are filled with asphalt to prevent leakage. The sloping floor performs the dual function of facilitating cleaning and of reducing the height of the wall sections.

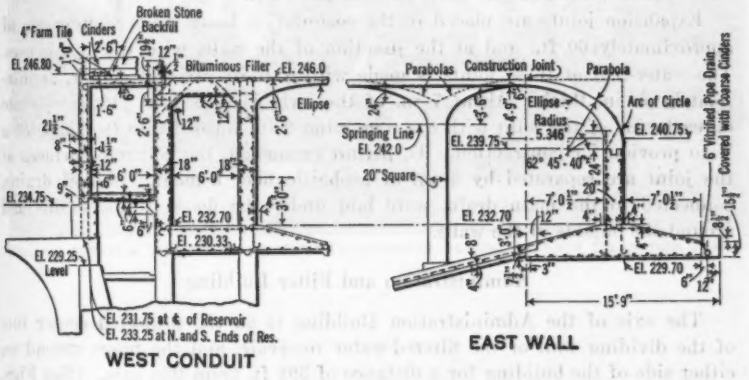

FIG. 3.—COAGULATION BASINS: DETAILS OF WEST CONDUIT AND EAST WALL.

All conduits (Fig. 3) were designed as rigid structures. Stability was investigated under conditions allowing an upward hydrostatic head of one-third the height of the water in the basin. In the case of the north conduit, recognition was taken of the possible removal of the earth backing at some future time to take care of adjacent construction, and the conduit was designed accordingly. At the by-pass conduit, the usual barrel arch was designed as a cantilever, extending from the roof of the conduit. Because of the frequency with which it has been observed that arch action does not always take place between the barrel and groined arches, all dividing walls between the basins were designed on the basis of an unbalanced arch thrust. The groined arches are tied together in groups of four and reinforced with two ½-in. square bars on either side of the crown. All manholes are tied securely to the groined arch roof with steel reinforcement extending well into the arches. This is required particularly in the case of the manholes supporting the mechanism for the mud-valves, in order to prevent frost action between the roof and manholes lifting the mud-valves off their seats in the floor of the basin, and thus permitting water to leak into the drains. The

columns supporting the roof are of five different lengths, varying from 10 ft. 8 in. to 17 ft. 11 in. In the 10 ft. 8-in. and 12 ft. 8-in. columns, no reinforcement is used. The remaining columns are reinforced with four ¾-in. square bars, with ¼-in. round ties spaced 12 in. center to center. Six stiffening walls are placed in each basin, parallel to the long axis, and near the center of the basin.

Each coagulation basin is provided with six mud-valves for cleaning and draining. These valves permit flow into a lateral drain placed immediately under the floor of the basin and along the longitudinal axis. Each drain is connected into the main drain header near the north end of the basin.

To assist in cleaning, 2½-in. hose gates spaced about 50 ft. from center to center are provided on each side of each basin. They are connected to 6-in. water mains placed on the long walls of the basins.

Expansion joints are placed in the coagulation basin walls at intervals of approximately 60 ft., and at the junction of the walls with the gate-houses. The water-seal at these joints is made with a 16-in. strip of copper, approximately $\frac{1}{8}$ in. thick. About 7 in. of the strip is embedded in the concrete on each side of the joint with the remaining 2 in. formed into the shape of a V to provide for contraction. To permit expansion, the concrete surfaces at the joint are separated by ⅝ in. of asphaltic fiber cement. Subsoil drains, connected to the main drain, were laid under the floors of the basins and around the outside of the walls.

## Administration and Filter Building

The axis of the Administration Building is on the projected center line of the dividing wall of the filtered-water reservoir, and the filters extend on either side of the building for a distance of 391 ft. from this axis. (See Figs. 1 and 5.) The south wall of the filters rests on the north wall of the reservoir, and provisions were made in the design so that a portion of the inlet control works of this reservoir forms the foundation for a part of the Administration Building.

*Administration Building.*—The Administration Building is a skeleton steel structure 166 by 71 ft. in plan and, approximately, 51 ft. in height from the main floor to the under side of the roof trusses. Below the main floor (Elevation 244) are a basement and an intermediate floor. The general offices are on the main floor, with the store rooms, transformer room, pipe shop, blacksmith shop, and chlorine room on the floor below (Elevation 234). The main piping, carrying the raw and filtered water, is on the lowest or basement floor. The floor containing the laboratories, general storeroom, and machine shop, and the drip floor, located just below the wash-water tanks, are above the main floor. Access is furnished to all these floors by stairs and a freight elevator.

The architectural arrangement is such that an elaborate stone double stairway leads to the main entrance to the building (Fig. 5), and advantage was taken of the space under this stairway for locating the wash-water pump-room. This room is 21 ft. 6 in. by 51 ft. 6 in. in plan, and access to it is by means of a tunnel from the basement of the Administration Building.

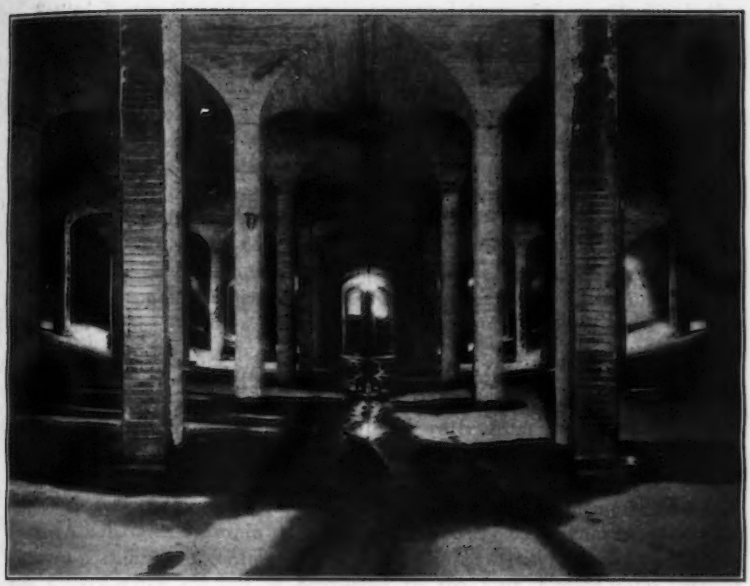

FIG. 4.—INTERIOR VIEW OF ONE OF THE COAGULATION BASINS, BALDWIN FILTRATION PLANT.

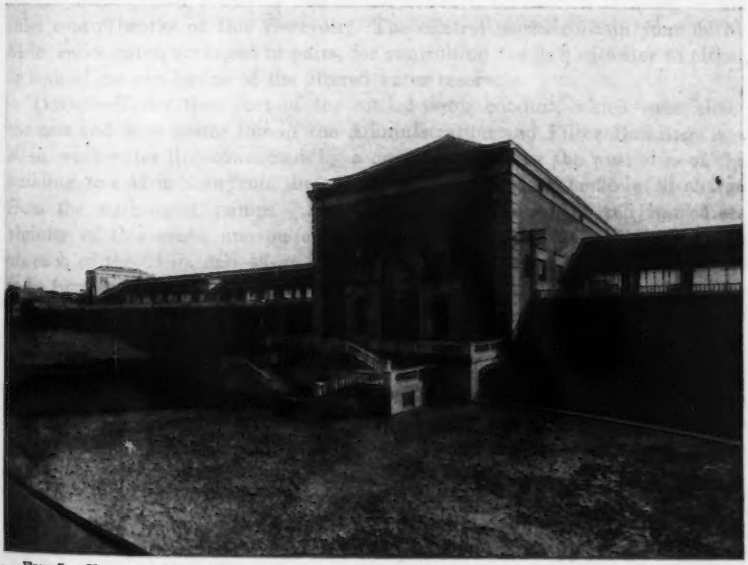

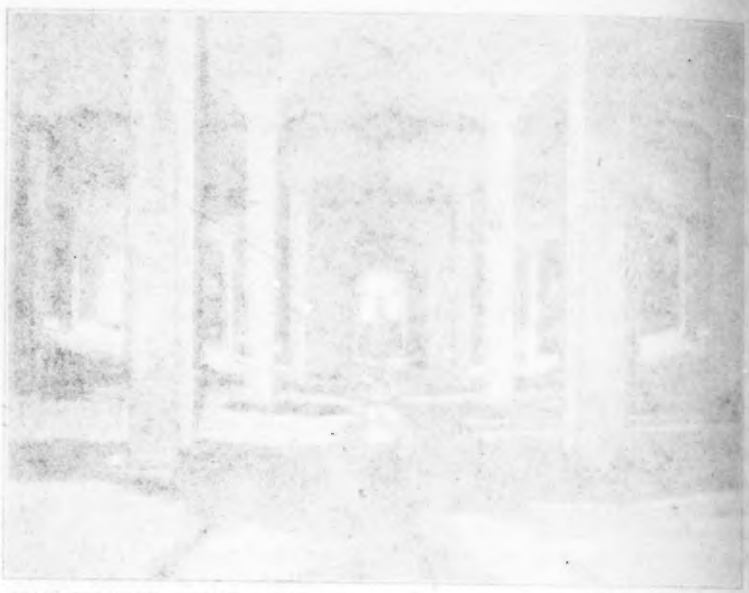

FIG. 5.—VIEW OF MAIN ENTRANCE TO ADMINISTRATION AND FILTER BUILDING, BALDWIN FILTRATION PLANT.

*Settled Water Conduit.*—Water is conveyed from the coagulation basins through a concrete conduit, 8 ft. wide by 13 ft. 5 in. high, north of and adjacent to the east wing of the filter building. (See Fig. 1.) This conduit terminates in a section, 14 ft. 5 in. wide by 13 ft. 5 in. high, just within the Administration Building. The top of this section forms a part of the floor at Elevation 234.0. This latter conduit is connected to the conduit that runs the length of the pipe galleries, by a short section of double-barreled conduit beneath the floor at Elevation 234.0. Within the pipe gallery, the conduit is 7 ft. wide by 8 ft. high. In the Administration Building, it is 11 ft. 3 in. wide by 5 ft. high. The conduits within the pipe galleries are connected to that within the Administration Building by means of transition sections. The change in the conduit dimensions was brought about by the need of conserving head-room in the Administration Building and width of gallery in the pipe galleries themselves.

*Filtered Water Conduit.*—Along the north and south center line of the Administration Building and resting upon the basement floor, is a reinforced concrete conduit for conveying the filtered water from the effluent galleries to the filtered-water reservoir. From the end of the conduit nearest the settled water conduit, a 54-in. by-pass is connected to the latter. This by-pass is controlled by two 48-in. valves, which are arranged with a spacer piece between them. A 2-in. open drain, in the bottom of the spacer piece, guards against the slightest possibility of contamination of the filtered water by the settled water. The filtered-water conduit is connected to the four filtered-water effluent galleries under the filters by 54-in. cast-iron pipe controlled by 48-in. valves. At the filtered-water reservoir end of the conduit, connection is made to the inlet control works of this reservoir. The control works contain four 60 by 84-in. sluice-gates, arranged in pairs, for controlling the flow of water to either or both of the two basins of the filtered-water reservoir.

*Piping.*—Under that part of the settled-water conduit, which runs along the east and west center line of the Administration and Filter Building, is a 30-in. wash-water line connected, by a cross located near the west side of the building, to a 42-in. line from the wash-water tanks and to the 24-in. discharge from the wash-water pumps. Four valves are grouped in the immediate vicinity of this cross, one on either side of it on the 30-in. line and one on each of the 24-in. and 42-in. lines. This arrangement permits wash-water to be furnished either from the tanks or from the pumps to the filters in either wing of the filter building. A man-hole and drain are also provided in the 30-in. wash-water line. In the 24-in. pump discharge, a Venturi meter is provided for measuring the flow of wash-water from the pumps.

A 30-in. cast-iron suction pipe is encased in concrete, under the floor of the basement. It continues under the floor of the tunnel and connects to the wash-water pump-room. This suction pipe is connected to sumps in the floors of two of the effluent galleries, each branch being provided with a 30-in. valve.

*Intermediate Floor.*—The intermediate floor at Elevation 234.0, is located at the level of the top of the settled-water conduit. On this floor are rooms for storing and applying chlorine, a transformer room, and pipe and blacksmith shops. All deliveries to the Administration and Filter Buildings are made to

this floor at a doorway beneath the main entrance. This door is reached by a semi-circular roadway passing under this entrance.

*Main Floor.*—On the main floor at Elevation 244.0, is the operators' room, in which are located various gauges. Adjoining this room is a dining room and kitchen for the use of employees. A drafting room, locker room, toilets, and space for a freight elevator complete the west half of this floor. Across from the operators' room in the southeast corner of the main floor, is an observation room, in which is located, open to public view, one of the system of weirs which admit water to Baldwin Reservoir. Adjacent to this room is a small assembly room. In the northeast corner of the building is a group of offices occupied by the superintendent and clerical forces.

*Laboratory Floor.*—On the laboratory floor at Elevation 258.67, are located the laboratories, machine shop, stock room, toilets, and locker room. The rooms used for chemical and bacteriological work include two chemical laboratories for water analysis, one for coal and oil testing, a preparation room for media, a bacteriological laboratory, a microscopic room, an incubator room, a refrigerator room, a photographic dark room, a library, and chemical storage rooms.

*Wash-Water Tanks.*—The two wash-water tanks are located on a steel grillage in the upper part of the Administration Building, with the bottom of the tanks at Elevation 281.12, or about 44 ft. above the maximum height of the wash-water troughs in the filters. These tanks are of steel-plate construction, each 60 ft. in diameter and 12 ft. deep, and are intended to operate with a maximum of 10 ft. of water. At this depth the capacity of the two tanks is 423 000 gal., or approximately the quantity required for six filter washes. A 36-in. cast-iron pipe leads from the bottom of each tank into a header, which discharges into a 42-in., vertical, pipe line, leading to the basement where it joins the 30-in. wash-water line in the pipe galleries. The pipe from each tank is provided with a 36-in. valve for controlling the flow. A 16-in. cast-iron overflow is installed in each tank. The entrance to this overflow is over a bellmouth piece with its weir edge placed 10.25 ft. above the bottom of the tank. In order to reduce the tendency to suck air caused by vortex action under low-water conditions, an inverted steel cone 3 ft. 10 in. in diameter and with the sides forming an angle of 45° to the base, was placed at the entrance to each 36-in. outlet. The apex of the cone is set in the plane of the bottom of the tank. In order to facilitate the maintenance of the steel tanks and the grillage, as well as to take care of condensation from the tanks, pipe, etc., a reinforced concrete floor with a proper system of drainage is placed under the tanks at an elevation of approximately 272.0 ft.

*Filter Building.*—The filters are housed in two wings of the Administration and Filter Building. (See Fig. 5.) These wings are each approximately 360 ft. long by 130 ft. wide and extend at right angles to the major axis of the Administration Building. Statistics relating to these units are as follows:

| | |
|---|---|
| Nominal capacity of filter beds, in million gallons per day | 165 |
| Number of filter beds | 40 |
| Capacity, in million gallons per day per filter | 4.16 |
| Rate of filtration, in million gallons per day per acre | 125 |

| | |
|---|---|
| Clear distance between weirs of the wash-water troughs, in feet | 4.93 |
| Capacity of wash-water troughs, in inches of rise per minute: | |
| With adjustable weir plates down | 24 |
| With adjustable weir plates up | 33 |
| Probable practical rates of rise, in inches of rise per minute: | |
| With adjustable weir plates down | 21 |
| With adjustable weir plates up | 26 |
| Wash-water capacity of main gutter, in inches of rise per minute. | 33 |
| Maximum velocity of flow through settled-water conduits, in feet per second | 2.42 |
| Maximum velocity of flow through 24-in. settled-water pipes, in feet per second | 2.04 |
| Elevations: | |
| Edge of wash-water troughs: | |
| Maximum | 236.92 |
| Fixed | 236.50 |
| Top of central gutter | 237.50 |
| Bottom of central gutter (sloped from Elevation 230.75) | 230.50 |
| Floor of effluent galleries | 216.0 |
| Floor of filters | 230.5 |
| Normal water-line in filters | 240.63 |
| Top of sand | 234.83 |
| Top of gravel | 232.33 |
| Floor of wash-water tanks | 281.12 |
| Overflow of wash-water tanks | 291.37 |
| Top of wash-water tanks | 293.12 |
| Filter sand: | |
| Depth, in inches | 30 |
| Effective size, range in millimeters | 0.35 to 0.42 |
| Uniformity coefficient | 1.70 |
| Filter gravel, depth of graded layers: | |
| Size, 1½ in. to ¾ in | 15 |
| ¾ in. to ¼ in | 3 |
| ¼ in. to ⅛ in | 2 |
| ⅛ in. to $\frac{1}{16}$ in | 2 |
| Total depth of gravel, in inches | 22 |
| Capacity of wash-water pumps, in million gallons per day: | |
| Two at 1 850 gal. per min | 5.33 |
| Two at 3 450 gal. per min | 9.94 |
| Total capacity of four pumps | 15.27 |
| Capacity of two wash-water tanks (water, 10 ft. deep) each tank, in gallons | 211 500 |
| Diameter of wash-water tanks, in feet | 60 |
| Total weight of one full tank (10 ft. of water), in tons | 946 |
| Average quantity of water required to wash one filter, in gallons. | 71 000 |

Each group of ten filters is built upon the roof of an effluent gallery or small filtered-water reservoir into which these filters discharge. The filter operating floor is located at the level of the top of the filters and spans the pipe gallery.

*Filter Tanks*—The filter tanks were designed to be built as monoliths. Each unit has a sand area of 1 450 sq. ft. divided into two equal areas by a center gutter. The outside walls of the tanks are designed as vertical slabs held at the bottom by the tank floor and at the top by the filter walks, acting as horizontal beams and as ties. The walks extend along the top of the four outside walls, over the central gutter, and at right angles to the center walk.

Wash-water gutters, running at right angles to the center gutter, are designed and arranged as shown in Fig. 6. Longitudinally, the slope of the bottom is 1 in. in the full length of the gutter.

The strainer system of the filter tanks is of the perforated-pipe manifold type, with the manifold located under the central axis of the sand bed in each half of the filter. The manifolds for each half filter consist of four independent castings, each having a central source of water supply. Each of the manifold castings supplies forty-two cast-iron laterals, arranged as shown in Fig. 6. In order to wash the otherwise dead area over the manifold, $\frac{3}{8}$-in. brass nozzles were provided, one nozzle being furnished for approximately 52 sq. in. of sand area over the manifold. The total area of the holes in the strainer system is 0.309% of the area of the sand bed. The area of the holes in one lateral is 36% of the cross-sectional area of the lateral, and the area of the laterals fed by one manifold is 71.4% of the cross-sectional area of the manifold. The effective length of the lateral is 29.5 times its diameter.

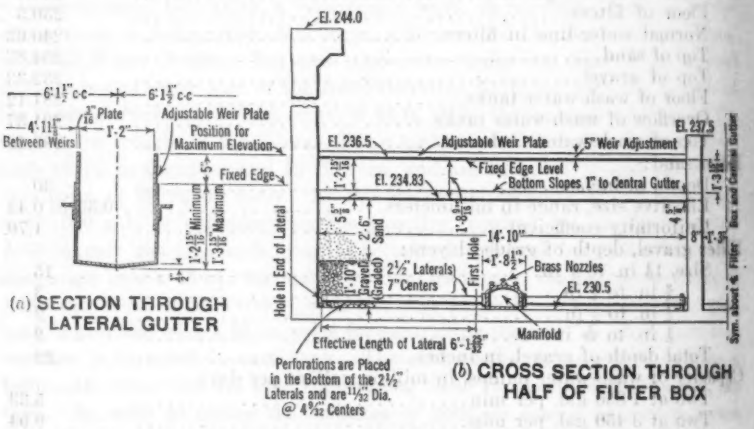

FIG. 6.—GENERAL CROSS-SECTION OF ONE-HALF OF A COMPLETED FILTER TANK.

The strainer system was designed in accordance with the results of experiments by one of the writers,[7] which were an extension of those made by Harry N. Jenks,[8] M. Am. Soc. C. E. The original design contemplated the use of flange connections for the laterals, but, on the basis of bids submitted, it was found that a considerable saving could be made by the use of the bell-and-spigot joint. To eliminate the possibility of slippage at the lead joint, a collar is cast on the lateral near the closed end. Cast-iron lateral chairs were designed to be slipped over the ends of the laterals as far as the collar and then to be bolted to the filter tank bottom. The manifolds are practically uniform in cross-sectional area. They are provided with hand holes near the end of

[7] "Design of Perforated Pipe Strainer System," by J. W. Ellms, M. Am. Soc. C. E., *Journal*, Am. Water Works Assoc., December, 1927.

[8] "An Investigation of the Efficiency of the Perforated Pipe Underdrain System in the Washing of Rapid Sand Filters," by Harry N. Jenks, M. Am. Soc. C. E., July, 1920.

each casting and with a 12-in. manhole at the center just over the inlet for the water supply.

*Effluent Galleries.*—The effluent galleries are four in number and each is 352 ft. 6 in. long. The two north galleries are each 47 ft. 6 in. wide and the south galleries, 45 ft. 3 in. wide. The distance from the floor to the under side of the roof is 13 ft. 3 in. The capacity of the four galleries is about 6 000 000 gal. Each gallery is provided with two 12-in. drains. These drains empty into the main drain and each is provided with two valves in series. A 24-in. flanged access manhole was provided in the common wall between the effluent and pipe galleries at about the mid-point in the length of the wall. At the ends of the galleries next to the Administration Building, sight wells, 4 by 5 ft. in plan, open into the effluent galleries. They permit observation of the filtered water during operation, and provide means of taking out any of the piping in the effluent galleries, in case such a need should arise. The piping in the effluent galleries, in conjunction with the strainer system, acts as the collecting system for the filtered water, conveying it from the filters through the controller in the pipe gallery and then back again into the open effluent gallery. The same system of piping in the effluent galleries serves for the distribution of the wash water during the washing process.

The floor of each effluent gallery rests on shale and is designed for a minimum thickness of 10 in. It is reinforced on the bottom with $\frac{5}{8}$-in. square bars, spaced on 6-in. centers and running in both directions. The footings for the columns supporting the effluent gallery roof with its superimposed loads, rest directly on this floor. To transfer the loads to the columns, large beams and girders were provided, those coming under the center line of the filters being 25 in. wide and 52 in. deep. The longitudinal walls of the effluent galleries were designed as slabs tied into the floor and roof. The walls at the extreme east and west ends were similarly designed, advantage being taken of the passive resistance of the earth against the wall. At the Administration Building, due to the lack of passive earth resistance to counteract the load transmitted by the wall to the roof, and to the existence of an expansion joint 73 ft. from the wall, special reinforcement was designed for the roof to transfer the load into the longitudinal walls.

To provide for temperature changes, expansion joints were placed 71 ft. apart. The joints are located immediately below the dividing plane between each group of two filters. The expansion joints extend from north to south across the entire building and from the roof of the effluent galleries down through the foundations. Copper plates were used at all expansion joints to prevent leakage of water. These plates were carried from the bottom of the foundations to the top of the filter tanks.

*Pipe Galleries.*—The pipe galleries occupy that space in the filter building between the two rows of filter tanks, and extend from the level of the effluent gallery floor to the operating floor. There are two galleries, each having the same length as the effluent galleries. The pipe galleries are 27 ft. wide and approximately 28 ft. high. In these galleries are the settled-water conduit and wash-water pipe, with connecting piping for each individual filter, and the filter rate controllers. An 8-in. water-pressure line and a steam-heating line

suspended from and approximately 3 ft. below the operating floor, run the entire length of the two pipe galleries and across the Administration Building.

The settled-water conduit is of reinforced concrete, rectangular in section, 7 ft. wide and 8 ft. high. It is supported by concrete columns spaced approximately 9 ft. apart. Expansion joints are placed nearly opposite those in the effluent galleries and 71 ft. apart. All expansion joints are located midway between columns, the conduit accordingly acting as a cantilever. The top of the conduit is at Elevation 237.0, and serves as a walkway along the entire length of the pipe gallery. This walkway is easily accessible from the floor level in the Administration Building at Elevation 234.0, the top of the transition section of the conduit at the entrance to each gallery serving as a ramp.

The main drain is a rectangular concrete conduit, the top of which is reinforced and serves as a part of the pipe-gallery floor. This conduit is designed to have the sides bear directly against shale. It is 5 ft. wide and, at the shallowest section, 5 ft. deep. The bottom has a slope of 0.00251 ft. per ft. When washing two filters at the same time, there is a slight upward pressure on a part of the drain roof. Because of this fact the floor drainage from the pipe gallery is not designed to discharge into the main drain, but to empty into a 12-in. cast-iron sub-drain. This sub-drain is laid with open joints, in crushed stone, under the bottom of the main drain, and discharges into it at a point on the slope beyond the filter building, where there is no danger of water backing into the pipe gallery.

The pipe-gallery floor is 10 in. thick and rests on the shale. It is of plain concrete, and slopes 3 in. in about 11 ft. from the effluent gallery walls toward the top of the main drain. A vertical drop of 3 in. is made at the junction of the pipe-gallery floor proper with the top of the main drain, thus forming a distinct drainage channel along the longitudinal center of the pipe gallery. This channel discharges into the floor drain sumps, spaced 140 ft. apart. The invert of the drainage channel slopes 3 in. in 70 ft. toward these sumps. These sumps are connected by 6-in. cast-iron pipe to the 12-in. cast-iron sub-drain, previously mentioned.

The wash-water pipe line is a 30-in. cast-iron bell-and-spigot main, located under the settled-water conduit, and supported on concrete beams spanning between the columns supporting this conduit. At the west end of the pipe gallery, the wash-water pipe line is connected to a 24-in service supply main, and this furnishes an additional or emergency source of wash-water supply.

The control of this supply of wash water is by means of an altitude valve. If this valve fails to close when the wash-water tanks are full, the supply is closed by an electrically operated gate-valve between the altitude valve and the wash-water tanks. This emergency valve may be controlled by floats in the wash-water tanks or by a push-button switch. It may also be operated manually by means of a hand wheel. Just outside the building, in a valve vault, is a 24-in. pressure-regulating valve, a 24-in. check valve, and an 8-in. emergency connection to a higher pressure water-supply main. The pressure-regulating valve is used to reduce the pressure in the service main to that required in the wash-water system. The 24-in. check valve was required to prevent the water from the 8-in. emergency connection from backing up into the lower pressure 24-in. service main.

The system of piping at each filter consists of a 24-in. influent line controlled by a valve of the same size, a 24-in. effluent line containing a filter rate controller and a 24-in. valve, a 24-in. wash-water line controlled by a valve of the same size, a 30-in. drain line with a 30-in. valve, and an 8-in. filtered-water waste line and valve. All the valves are of the double-disk, parallel-seat type, and all are hydraulically operated except the hand-operated 8-in. filtered-water waste valve.

All valves, 24 in. and larger, where placed horizontally on their sides, are provided with rollers and scrapers. The 30-in. drain valves which have their disks in a horizontal plane, are provided with special heavy bronze mounted slides, operating on bronze tracks built in the body and bonnet of the valve, in order to prevent the wearing of the gate and seat rings. Just before the disks come to a stop, the tracks slope to permit them to drop into a closing position before the wedging mechanism operates.

Special precautions were taken to prevent the scouring of the brass lining by iron rust in the hydraulic valve cylinders. The cast-iron piston, which consists of two rings with a spacer, is provided with cup leathers, and is secured to the stem with bronze lock nuts. The circumference and upper and lower faces of the spacer or piston head, not in contact with the cup leather and followers, are covered with a brass facing, forced into place and securely fastened to the spacer.

The 8-in. pressure line running longitudinally through the pipe galleries, supplies water for operating the hydraulic valves. To avoid shutting down a considerable number of filter units due to a break in this line, it is fed from either end, and valves are placed at the quarter-points. At each end of the line, pressure-regulating valves are provided to reduce the pressure to that required for operating the hydraulic valves. The waste from all the hydraulic valves of each filter is piped to the central gutter of the particular filter to which they belong.

*Operating Floor.*—The operating floor is at the same elevation as the top of the filter tanks. It is of reinforced concrete, 7 in. thick, with quarry tile surfacing. It is supported on columns resting on the outer walls of the settled-water conduit, and at the filters on ledges constructed as a part of the individual filter tanks. Access from this floor to the top of the settled-water conduit as well as to the floor of the pipe gallery is provided at the ends of the pipe galleries by reinforced concrete stairs.

To provide light and air in the pipe galleries, openings 7 ft. wide by 17 ft. long, are located in the operating floor. These openings are centered on the dividing line between adjacent pairs of filter tanks. An ornamental iron rail follows the outline of the openings in the floor and continues, between openings, along the edge of the filter tanks. Easy access from the operating floor to the walks over the filter tanks is provided by means of gates.

## Baldwin Reservoir

*General Description.*—As previously noted, the Baldwin Reservoir was originally planned as a distributing reservoir for the low-service district. The original design was based on a 130 000 000-gal. open reservoir. The

excavation was about three-fourths completed when it was decided by the City of Cleveland to construct a filtration plant immediately adjacent to the reservoir, using it as the clear-water basin for this plant. Due to the fact that the excavation was so far advanced, the elevation of the bottom as well as the slope of the floor and the area to be occupied by the reservoir was fixed in a general way.

Baldwin Reservoir, as constructed, is about 1 035 ft. by 550 ft. in plan, and 40 ft. from the floor to the crown of the groined arch roof. The reservoir is divided into two basins of equal size. The maximum depth of water is 36.5 ft. in each basin, and the two basins have a total capacity of 135 000 000 gal. In all, there were 1 196 columns, the dimensions of which are shown in Fig. 7.

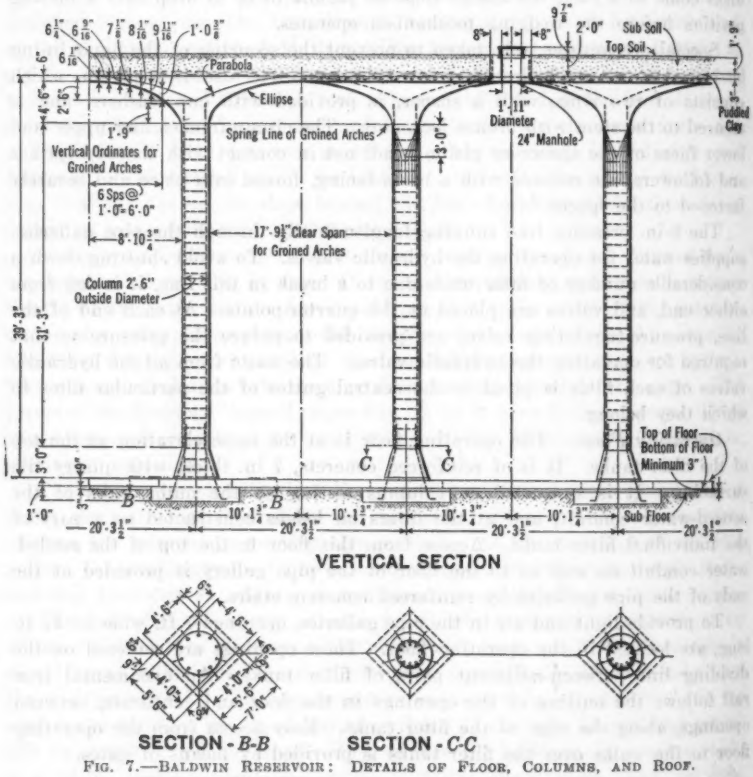

FIG. 7.—BALDWIN RESERVOIR: DETAILS OF FLOOR, COLUMNS, AND ROOF.

*Conditions Assumed for Design.*—Before the actual design of the various parts of the reservoir was begun, a careful study was made of the loads which might be imposed upon them during construction, as well as those which might be expected after the work was completed.

The conditions assumed for design before the completion of the reservoir, were:

1.—That the outside walls would be constructed and the back-fill placed against them before the roof arches were built.

2.—That the outside walls would be constructed and the roof arches built before any back-filling was placed against the walls or on the roof.

3.—That the concrete structure would be completed without the back-fill placed against the walls, or on the roof, and that either or both basins would be full of water.

The conditions assumed for design after the completion of the reservoir, were:

4.—That the concrete structure would be completed; that all the back-fill would be placed against the walls and on the roof; that there would be a uniform live load of 100 lb. per sq. ft.; but that there would be no water in either basin.

5.—That the same conditions would exist as are noted for Condition 4, except that either or both basins would be full of water.

In order to provide flexibility in operation and insure circulation of filtered water within the reservoir and also to detect leakage, it was assumed:

6.—That water would be delivered to either or both basins of the reservoir from the City's distribution mains prior to the completion of the Baldwin Filtration Plant.

7.—That water would be delivered to either or both basins of the reservoir from the filtration plant.

8.—That filtered water would be delivered to any or all of the distribution mains leading to the city and to the suction mains leading to the pumping stations from either or both of the basins.

9.—That means would be provided for emptying either basin for the purpose of cleaning or inspecting it and without disturbing the operation of the other basin.

In addition to the special features of design previously mentioned, careful consideration was given to circulation of the filtered water through each basin; to facilities for detecting leakage through the floor and lower sections of the walls; and to ample overflow capacity.

*Reservoir Floor.*—The floor of the reservoir slopes about 6 in. in 100 ft. from the north and south sides toward the center. The footings of all columns and stiffening walls were made separate from both the sub-floor and the finished floor. The sizes of the column footings were varied to suit the conditions of the shale, the smallest being 5½ ft. square, and the largest, 7 ft. square. In order to prevent the shale from disintegrating, and also to insure a uniform thickness for the finished floor, a sub-floor, having a minimum thickness of 3 in., was placed upon the shale immediately after the excavation was completed. No provision for expansion or contraction was made in the sub-floor. All irregularities in the excavation were filled with concrete.

The finished floor (Fig. 7) is 9 in. thick, and expansion joints are provided on the center lines of columns, namely, 20 ft. 3½ in. apart. The expansion joints consist of strips of prepared asphalt filler, 5 in. wide and ⅝ in. thick, placed at the bottom of the joints, the upper 4 in. being filled with hot asphalt. No steel was used in the finished floor except over the drains.

*Columns.*—In designing the connection between the tops of the round columns and the bottoms of the groined arches at their springing lines, a departure was made from usual engineering practice, in that the 2 ft. 6-in. round columns were flared out to a 2 ft. 6-in. square, which is the size of the groined arches at their springing lines. The ratio of length of column to outside diameter is 13.7 and the ratio of length of column to effective diameter is 15.75.

The maximum load on top of each column is about 184 000 lb., and the weight of each column is about 27 000 lb., making a total load of about 211 000 lb. on each column footing. Each column is reinforced with ten ¾-in. square twisted bars, placed 2 in. from the surface of the concrete. These bars are tied together with ⅜-in. round hoops, spaced 1 ft. on centers.

*Groined Arch Roof.*—Owing to the unusual depth of the reservoir, necessitating very long columns for supporting the roof, considerable thought was given to the most economical type of roof construction. Studies were made of several types of flat-slab design as well as of groined arches of various dimensions. These various designs were carefully compared as to cost, which led to the decision to use a groined arch roof with dimensions as shown in Fig. 7. The average thickness of concrete in the roof above the springing line of the groined arches is $8\frac{7}{16}$ in.

The method of calculating the stresses in the groined arches was based on the hypothesis of least crown thrust, as most generally used in theories of the voussoir arch. The total load on each arch was assumed as acting between vertical planes passed through the groins formed by the intersection of two adjacent arches, these planes intersecting at the center line of columns.

The line of thrust at the crown of the groined arches was assumed as acting through the upper third point. With this condition assumed, the least crown thrust to hold the groined arch in equilibrium under a maximum load of 2 ft. of fill and a live load of 100 lb. per sq. ft., produced a maximum compression of about 225 lb. per sq. in. in the concrete at a section about 6 ft. from the crown. The line of thrust at this point passes through the lower third point. The maximum shear is about 48 lb. per sq. in. under the same condition of loading. The upward pressure of the water did not affect the maximum compression in the arches, as this occurred at a point above the water level; but the maximum shear was slightly reduced.

Another feature in connection with the design of the roof to which special attention is called is the location of the stiffening walls (Fig. 8), which were provided to take the arch thrust in case of failure of a part of the roof. The two basins of the reservoir are each approximately 500 by 500 ft. and the two lines of stiffening walls in each basin divide the roof areas into approximately 250-ft. squares. The location of the stiffening walls does not interfere in any way with the circulation of the water across the basins. Their foundations and the two adjacent column foundations were designed to be poured monolithically, as were also the stiffening walls and the two adjacent columns.

Four ⅝-in. square bars were placed in the crowns of the arches, and sections containing not less than four groined arches were tied together by this steel. Construction joints in the roof were always placed at the crown, midway between columns. In order to prevent surface water from entering the reser-

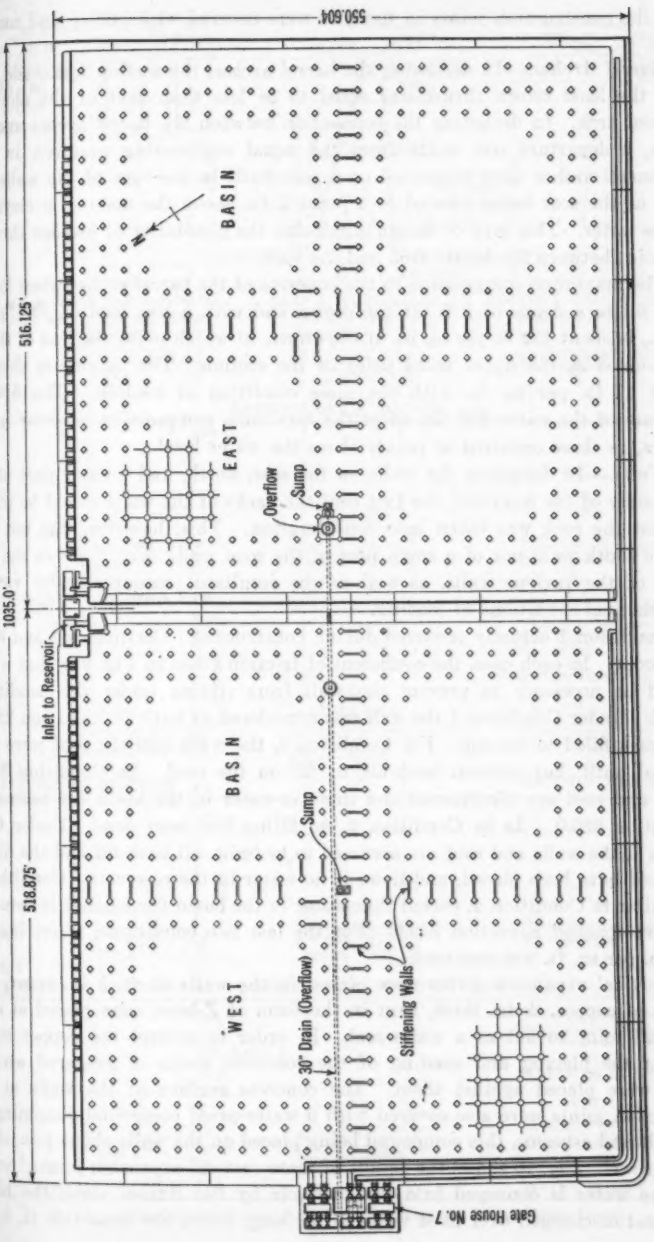

FIG. 8.—PLAN OF FLOOR, BALDWIN RESERVOIR.

voir the construction joints in the roof were covered with burlap and coal-tar pitch.

*Barrel Arches.*—In designing the barrel arches, the section was made such that the least crown thrust was equal to or less than that of the abutting groined arch. In designing the connection between the barrel arches and the walls, a departure was made from the usual engineering practice, in that the barrel arches were supported on a seat built in the tops of the walls, the back of the seat being carried to a point 3 in. above the maximum elevation of the water. This type of design eliminates the possibility of leakage through the joint between the barrel arch and the wall.

The maximum compression in the concrete of the barrel arches when loaded with fill to a depth of 2 ft. at the crown and with a live load of 100 lb. per sq. ft., is about 130 lb. per sq. in. at the crown, at which point the line of thrust is assumed at the upper third point of the section. The maximum shear is about 17 lb. per sq. in. with the same condition of loading. The upward pressure of the water did not affect the maximum compression or shear in the arches, as these occurred at points above the water level.

*Walls.*—In designing the walls on the east, north, and greater part of the west sides of the reservoir, the fact that the backs of the walls would be placed against the rock was taken into consideration. This, however, was not true of the south wall, nor of a small part of the west wall. Fig. 9 shows the outlines of the various walls, as well as the resultant pressures under various hypothetical conditions of loading.

Condition 1 actually occurred during construction; Conditions 2 and 3 did not occur. In each case, the coefficient of friction given in Fig. 9 is that which would be necessary to prevent the wall from sliding under the conditions noted. Under Condition 1 the wall was considered as built to Elevation 229.25 and back-filled to the top. For Condition 2, the walls and the roof were considered built, but without back-fill, or fill on the roof. In Condition 3 the walls and roof are constructed and there is water in the basin (or basins) to Elevation 225.0. As in Condition 2, no filling has been done. Under Condition 4, the walls and roof are assumed to be built, all back-fill and the fill on the roof have been placed, and there is no water in the reservoir. Condition 5 is similar to Condition 4, except that water in the basin (or basins) is assumed to have reached Elevation 229.0. For the last two conditions, a live load of 100 lb. per sq. ft. was assumed.

Vertical expansion joints were placed in the walls 81 ft. 2 in. apart, and strips of copper, $\frac{1}{8}$ in. thick, bent in the form of Z-bars, were placed at each vertical joint to act as a water-seal. In order to protect the copper strips during the placing and spading of the concrete, strips of prepared asphalt filler were placed against them. The concrete surface of the walls at the expansion joints were also covered with a water-proof compound consisting of asphalt and asbestos, this compound being placed on the walls about $\frac{1}{2}$ in. thick by a trowel. Fig. 10 shows the details of these vertical expansion joints.

The water is conveyed into the reservoir by two flumes along the north wall and discharged over fixed weirs, 13 ft. long, which are spaced 40 ft. 7 in.,

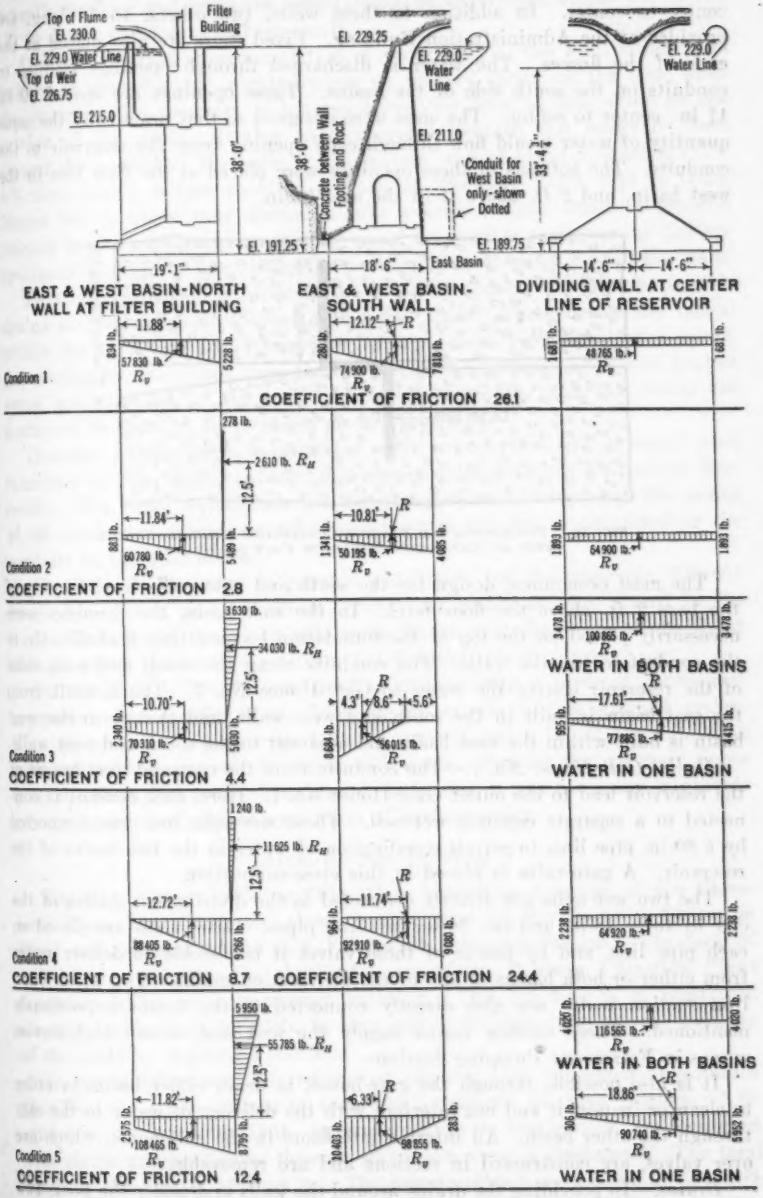

FIG. 9.—OUTLINE OF WALLS AND DISTRIBUTION OF FOUNDATION LOADS.

center to center. In addition to these weirs, two others, 15 ft. long, are provided at the Administration Building. Fixed weirs are also placed at the ends of the flumes. The water is discharged through openings leading to conduits on the south side of the basins. These openings are spaced 10 ft. 1¾ in., center to center. The sizes were designed so that practically the same quantity of water would flow through each opening from the reservoir to the conduits. The bottoms of these openings were placed at the floor line in the west basin, and 2 ft. above it in the east basin.

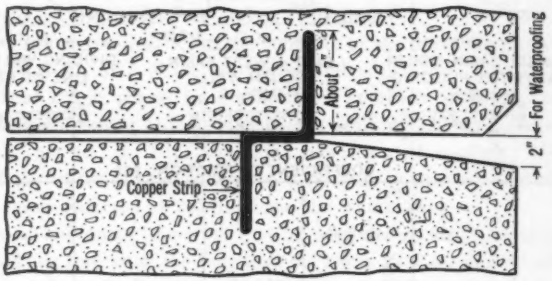

FIG. 10.—SUGGESTION FOR PLACING CONTINUOUS VERTICAL COPPER STRIP AT EXPANSION JOINTS ON FACE OF WALLS.

The most economical design for the south and west walls fixed the top of the base 2 ft. above the floor level. In the east basin, the openings were necessarily placed on the top of the foundation because they lead directly to the conduit within the walls. The conduits along the south and west sides of the reservoir convey the water to Gate-House No. 7. The conduit from the east basin is built in the south and west walls, and that from the west basin is built within the west basin and adjacent to the south and west walls.

*Outlet Gate-House No. 7.*—The conduits from the east and west basins of the reservoir lead to the outlet Gate-House No. 7. Here, each conduit is connected to a separate concrete wet-well. These wet-wells are cross-connected by a 60-in. pipe line, to permit equalization of water in the two basins of the reservoir. A gate-valve is placed in this cross-connection.

The two wet-wells are directly connected to the distribution system of the city by three 48-in. and two 36-in. cast-iron pipes. Gate-valves are placed on each pipe line, and by means of these valves it is possible to deliver water from either or both basins to any of the distribution mains. Two 48-in. cast-iron suction mains are also directly connected to the conduits previously mentioned. These suction mains supply the first and second high-service pumps in Fairmount Pumping Station.

It is also possible, through the gate-house, to drain either basin, in order to clean or inspect it and not interfere with the delivery of water to the city through the other basin. All intermediate floors in the gate-house, which are over valves, are constructed in sections and are removable.

*Drains.*—In providing the drains around the walls and under the floor, two objects were in view: (1) To prevent an accumulation of water under pressure

beneath the floor and excessive accumulation of water back of the walls; and (2) to detect and locate leakage easily.

It is obvious that an accumulation of water back of the walls either from leakage or ground-water might produce an upward thrust on the floor when the water in the reservoir is lowered below the level of the water on the outside of the walls. Drains were provided beneath the reservoir floor, around the outside of the walls at the bottom, and at about Elevation 211.0. All these drains, except parts of the one at Elevation 211.0, lead to Gate-House No. 7, where they discharge into a sump. Each drain is properly marked in the gate-house, so that it would be possible to determine the approximate location of any leakage or accumulation of water behind the walls.

Particular attention is called to the detail in connection with the outside drains at the bottom of the east and north walls. These drains are placed within the walls, and are all cast-iron bell-and-spigot pipe with leaded joints. At varying intervals (not more than about 80 ft.) pockets, filled with broken stone, are provided in the rock backing of the walls, and the drains are connected to them by short pieces of cast-iron pipe.

*Overflow.*—Each basin is provided with an overflow and a sump, each connected to the 30-in. cast-iron pipe drain which leads to Fairmount Reservoir. The sump connections are for the purpose of emptying the basins of all water that cannot be taken out through the drains connected to the conduits at the gate-house.

*Ventilation.*—In order to provide ventilation for the reservoir, fifty-six 24-in., four 36-in., and two 48-in., ventilating manholes were placed in the roof. Those along the north side were placed over the weirs of the flume through which the water flows from the filtration plant.

*Fill on Roof.*—The concrete roof is covered with a layer of thoroughly compacted clay puddle, 6 in. thick at the crowns of the groined arches. This, in turn, is covered with 1 ft. of sub-soil and 6 in. of top-soil. The entire top of the reservoir is seeded with grass. Because the reservoir slopes from the north and south sides toward the center, it was necessary to provide a drain to carry off any accumulation of surface water.

## Alum Storage Building

The alum storage building (Fig. 1) is located on a switch of the Cleveland Short Line Railroad, about ¼ mile west of the Baldwin Filtration Plant and adjacent to the new Fairmount Pumping Station. The lack of railroad connection to the chemical house of the Baldwin Filtration Plant necessitated this separate storage building. This building is of reinforced concrete and is 51 ft. by 87 ft. in plan and 43 ft. high. The storage capacity of the building is about 1 000 tons.

In the building are four reinforced concrete bins supported on columns (see Fig. 11). The bottom of each bin terminates in three hoppers, 16 ft. square at the top with 15-in. square openings in the bottom, and equipped with single undercut gates through which the alum is discharged. The total depth of the bins is 17 ft. 6 in. The hopper sides have a slope of 50° with the horizontal. The bins extend across the building, and a common dividing

wall separates one bin from another. The entire area under the bins is used for truck runways.

## Construction

The construction of Baldwin Filtration Plant was carried on under general contracts for the different parts of the work. The construction operations will be described in the order in which they were done.

### Baldwin Reservoir

In the winter of 1914-15, the City, by direct labor, began preliminary work by stripping the top-soil from the site of a proposed 130 000 000-gal. open reservoir. On April 9, 1915, a contract was awarded for the excavation of this reservoir. The contractor had completed about three-fourths of the work when he encountered financial difficulties and, as a result, suspended operations in July, 1918. All the excavation remaining to be done was in solid rock and, in consequence, the City entered into a "cost-plus" agreement with a quarrying company to complete the work. Excavation was resumed in the winter of 1918-19, and completed in 1920, except for final trimming.

During the period covered by the excavation work, the location of the proposed second filtration plant, as explained under "History and Development of the Project", had been changed to the Baldwin site. Accordingly, additional land was purchased on either side of the reservoir, and this extended the area of city-owned land to the streets surrounding the site.

Bids were received and a contract for the construction of the reservoir was entered into on May 27, 1921; but objection was taken to this award and it was annulled by the Courts. The work was re-advertised, bids were received again, and the contract was awarded to the low bidder on November 18, 1921.

While the contractor was assembling his construction plant, he began the final trimming within the reservoir, and the final excavation for the wall footings. Due to the disintegration of the shale on exposure to air, it was necessary to leave the final trimming of all excavation until just prior to placing the concrete.

Pending the erection and completion of the central concrete mixing plant and the Lidgerwood 15-ton cableway, the contractor erected a temporary mixing plant within the reservoir excavation, near the south wall. Concrete mixed at this plant was hoisted to the top of a steel tower and distributed by chutes. By this means concreting of the south wall was commenced in the spring of 1922.

After the completion of the central mixing plant and the cableway, the temporary mixing plant was dismantled. After this, all concrete was mixed at the central mixing plant, and distributed by the movable cableway. The cable spanned the work in a north and south direction and was capable of movement in an east and west direction over the entire length of the reservoir. Work on the floor, column foundations, and columns, and on the groined arch roof, was started along the east wall and progressed toward the west.

FIG. 11.—GENERAL SECTIONS, ALUM STORAGE BUILDING.

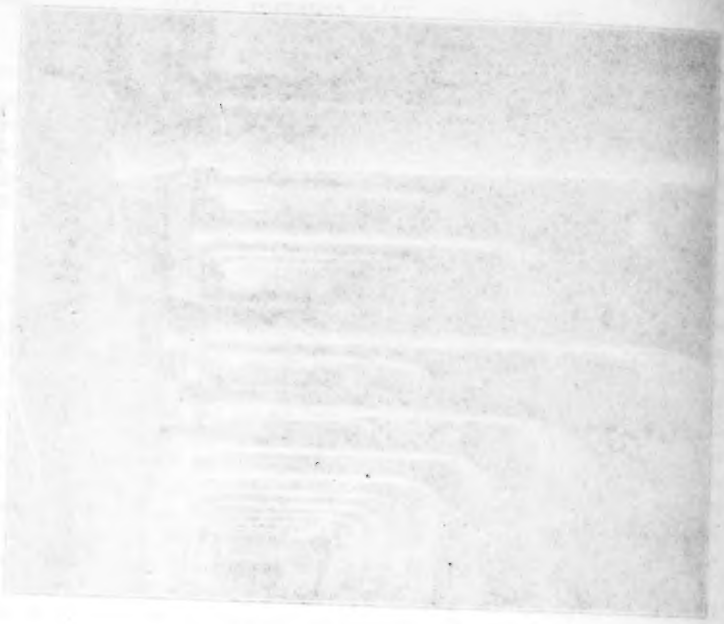
Work was continued night and day during 1922, until the winter weather stopped operations in December. At this time the entire roof of the east basin had been completed and a good start had been made on that of the west basin. Concreting was resumed in the following April, and the entire work, except for the completion of the rough grading, was completed in the late summer of 1923. Fig. 12 is a view of the construction work and Fig. 13 shows an interior view of the completed structure.

## Construction Plant

*Cableway.*—The layout of the construction plant is shown on Fig. 14. The 15-ton cableway was electrically driven. All operations of carriage, lifting hook, and both towers were controlled by one operator on the head tower. The main cableway hoist motor was an induction motor (440-volt, 300-h.p., at 950 rev. per min.). The motors for moving the head and tail-towers longitudinally along the tracks were considerably smaller (440-volt, 75-h.p., at 1 150 rev. per min.). The main cable was 2½ in. in diameter. The head and tail-towers were of wood construction, 85 ft. high, and all timbers were of full length without splices. The cableway towers traveled on standard freight-car wheels and axles. The track was composed of five 100-lb. rails, with a distance between the first and fifth rails of 40 ft. 2 in. The cableway was capable of handling a 7-cu. yd., bottom-dump, concrete bucket.

*Central Concrete Mixing Plant.*—The concrete mixing plant (see Fig. 14) was 30 ft. by 63 ft. in plan and 55 ft. high. It was of wood construction, except that the beams supporting the overhead material bins were of steel. The coarse and fine aggregate was delivered to the mixing plant in hopper-bottom cars of standard gauge, which were dumped from a material trestle, 250 ft. long and 22 ft. high. The material was lifted from the receiving hoppers beneath the trestle to the bins above the batch-measuring hoppers by three bucket elevators, 90 ft. long. The buckets were mounted on a 15-in. belt. Each elevator had a capacity of 75 tons per hour. Two of the bucket elevators were used for conveying stone and one for sand. Each elevator, together with its feeder conveyor, was driven by a 20-h.p. motor.

Cement was delivered in sacks in cars on a track ending at the east side of the mixer building. This track was located at such an elevation that the floor of the cement cars was on a level with the operating and cement storage floor of the mixer building. Platforms were provided along both sides of the cement tracks so that the cement could be moved by warehouse trucks directly from the car to the mixers or to storage.



The two hopper-bottomed overhead stone bins had a capacity of about four cars each, and the one similar bin for sand had a capacity of about six cars. The sand bin was located between the two stone bins. Concrete was mixed in two 1-yd. mixers, driven by 30-h.p. motors. Material was drawn by gravity from the bins directly into bottom-dumping steel measuring boxes. Water was supplied from measuring barrels, equipped with gauge glasses. Each set of measuring boxes discharged into a steel receiving hopper, which, in turn, emptied into the body of the mixing drum. Cement was dumped from bags through a grating in the floor of the storage room directly

FIG. 12.—VIEW SHOWING BRACING AT TOPS OF CONCRETE COLUMNS, PREVIOUS TO PLACING FORMS FOR ARCHES, BALDWIN RESERVOIR.

FIG. 13.—INTERIOR VIEW OF BALDWIN RESERVOIR.

into this receiving hopper. As a result of this arrangement, the sand, stone, cement, and a measured quantity of mixing water were supplied to the mixer simultaneously. The mixers were discharged into a common conical steel hopper with a capacity of about 9 cu. yd. A slide-gate at the bottom of this hopper permitted the concrete to be discharged into the 7-yd. concrete bucket as needed.

*Placing Concrete.*—The concrete was poured from 7-yd. buckets. After the buckets were filled they were transported on flat cars running on narrow-gauge (36-in.) tracks. Locomotives hauled the loaded cars to a position under the cableway, which had been previously moved so as to span over the form to be filled with concrete. An emptied bucket, hanging on the cableway hook, was placed on an empty flat car, and the full bucket of concrete was then picked up by the hook and moved to the proper position directly over the form and lowered to position for pouring. During the time that the bucket was being moved along the cable, the empty bucket was on its way to the mixer for refilling.

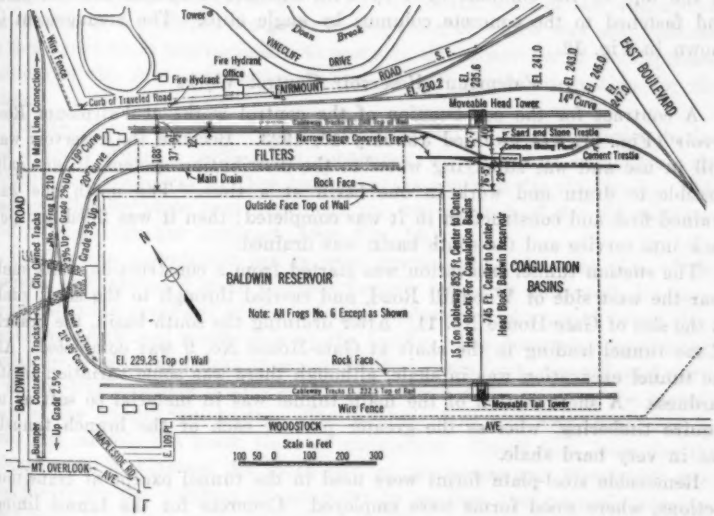


FIG. 14.—COAGULATION BASINS AND FILTERS, CONSTRUCTION PLANT LAYOUT.

*Forms for Concrete.*—Considerable study was given to the design of forms, in order to keep costs as low as possible. Practically all forms were made in separate panels so as to permit their use many times. Wall-form panels were made of various sizes, depending on their intended use. The largest single panels were about 20 ft. high and 45 ft. long. Forms for the groined arch roof were made in four sections for the part supported by one column.

Except for columns, all forms were made of $\frac{7}{8}$-in. center-matched lumber, nailed to 2 by 6-in. studs which were spaced on 16-in. centers. Vertical

forms were braced by 4 by 6-in. timbers running horizontally outside the studding and held from spreading under the force of the horizontal thrust of the wet concrete, by ⅞-in. bolts running through the section to be concreted. These bolts were made up with pump-rod couplings, spaced 4 in. inside of each form face. These horizontal timbers were spaced a variable distance apart, depending on their elevation above the bottom of the form. Column forms were made of steel, each complete form consisting of two halves. All forms were handled by the cableway.

Due to the great depth of the reservoir, unusual methods were used in supporting the forms for the groined arch roof. The entire load of the roof forms as well as of the concrete, was carried by wood and steel collars fastened around the tops of the previously poured columns, and by eight wooden posts, each 8 in. square, extending from floor to roof, and located around the perimeter of the groined arch unit supported by one column. One post was located at each of the four corners, and additional posts midway between the corner posts. These posts were braced in a horizontal plane at the tops of the columns by 4 by 6-in. timbers, extending between posts and fastened to the concrete columns by angle clips. The arrangement is shown in Fig. 12.

## Fairmount Reservoir Control Works

A contract for the construction of the control works at Fairmount Reservoir (Fig. 1), was awarded January 15, 1923. Because the reservoir was still in use and was supplying water to the distribution system, it was only possible to drain and work in one basin at a time. The north one was drained first and construction in it was completed; then it was filled and put back into service and the south basin was drained.

The suction tunnel excavation was started from a construction shaft sunk near the west side of Woodhill Road, and carried through to the shaft sunk at the site of Gate-House No. 11. After draining the south basin, the branch of the tunnel leading to the shaft at Gate-House No. 9 was completed. All the tunnel excavation was in shale, although there was some variation in its hardness. A short section of the main tunnel was in material so soft as to require timbering, whereas the greater part of each of the branch tunnels was in very hard shale.

Removable steel-plate forms were used in the tunnel except at transition sections, where wood forms were employed. Concrete for the tunnel lining was mixed at the top of the construction shaft in a drum mixer and was transported to the point of placing by a pneumatic concrete blower, which forced the mixed concrete through a 4-in. steel pipe line.

## Coagulation Basins

*Excavation.*—The excavation for the coagulation basins was done under a contract, bids for which were received April 29, 1920. The contractor began work June 25 of the same year and continued working until March 8, 1921. The area covered by the basins was excavated to an elevation 1 ft. above the base of the proposed wall foundations. The material encountered was clay and soft shale. Steam shovels loaded the excavated material into

dump trucks and dump wagons, which removed it to storage and disposal piles.

Three steam shovels were used regularly on the work. The maximum number of dump trucks used in any one day was twenty-three and the maximum number of teams was thirty. Progress of the work was greatly delayed in wet weather, due to the inability of the trucks and teams to maneuver in the wet clay.

The total material excavated was approximately 117 000 cu. yd. About 20 000 cu. yd. suitable for back-filling were hauled to a storage pile across Doan Brook and about 1¼ miles east of the site of the work. An additional 10 000 cu. yd. were used in completing a fill along the south side of Doan Brook, and in the landscaping plans in the development of the valley of this brook. An additional 30 000 cu. yd., suitable for back-filling, as well as about 55 000 cu. yd. intended for use as clay puddle on the roof of the filtered-water reservoir, were stored between the site of the basins and the boulevard to the east.

Due to delay on the part of the City in acquiring some of the land needed for the site of the filters—the general excavation of which was also included in this contract—it was necessary to postpone the excavation of the depressed portions of the four coagulation basins, as well as the excavation for the filters.

*Construction.*—A contract for the construction of the coagulation basins was awarded June 1, 1923. The contractor who was just completing the Baldwin Reservoir, was the low bidder on the contract for this work. This made possible, by some re-arrangement, the use of much of the old construction plant on the new contract. (See Fig. 14.)

Because the coagulation basins were located along the east side of the reservoir and extended some distance beyond its north and south limits, a direct extension eastward of the existing cableway tracks would bring them inside the north and south ends of the basins. The contractor accordingly moved the head-tower tracks to a new position, parallel to the old, and north of the existing concrete mixing plant, and extended the track to the easterly limit of the coagulation basins. The mixing plant had been purposely located just outside the north limit of excavation. Insufficient room for the tail-tower tracks, between the south wall of the basins and Woodstock Avenue, prevented the location of these tracks so that the cableway carriage could span the full length of the basins. However, the existing tail-tower tracks were extended east over the south end of the basins for their full width. This arrangement placed the entire coagulation basin area, except the part at the southerly end, within working position of the hoisting hook on the cableway carriage. The increased span necessitated the substitution of a 5-cu. yd. bucket in the place of the 7-cu. yd. bucket used on the reservoir, thus reducing the capacity of the cableway to about 12 tons.

After completing the re-arrangement of the construction plant, the contractor excavated for and placed the concrete foundation for a considerable length of the by-pass conduit. At the same time a ¾-yd. caterpillar steam shovel was used in excavating the depressed portion of Basin No. 1. When

considerable of this basin had been excavated to within a few inches of the final grade, a steam channeling machine was set up over the location of the longitudinal drain, and channel cuts were made along each side. After excavating, this method left the walls of the drain in good condition to receive the concrete lining, using only interior forms and depositing the concrete directly against the shale through which the channel cuts had been made. This practice of making cuts through the shale and rock and depositing concrete directly against the vertical surface was typical for similar conditions throughout the work. It was of particular value in situations like the one before mentioned, where no back-filling could be permitted behind the drain walls on account of possible settlement and resultant cracking of the basin floor.

At the same time that the longitudinal drain was being built, foundations for the dividing wall between Basins Nos. 1 and 2 and the column foundations for Basin No. 1 were constructed. After concreting the drain walls, dividing wall, and column footings for a sufficient length of basin, the last few inches of shale were removed from the general floor area and 4 in. of sub-floor concrete were placed. This concrete formed a working base on which the steel for the finished floor could be placed, and insured that the full depth of concrete for this floor would be free from disintegrated shale. If the sub-floor had been omitted, it would have been possible for serious disintegration of the shale to have occurred during the placing of the floor steel. This shale might have worked up into the floor concrete while it was being placed, thus forming weak spots.

At all construction joints in the floor-slab, as well as where the floor concrete joined the column and wall foundations, particular care was taken to insure water-tight joints. Before pouring the floor, strips of prepared asphalt filler $\frac{3}{4}$ in. thick were placed at the bottom of the joints. These extended to within 4 in. of the floor surface. In the upper part of the joint, flat steel plates were placed. They were withdrawn after the concrete had set, and the space was filled with melted asphalt. This type of joint was used throughout the work in locations requiring a water-tight floor joint. In addition, all vertical joints in the floor and sub-floor were staggered at least 12 in.

At the transverse joints in the wall and conduit foundations, copper strips provided adequate water-stops, and the poured asphalt joints were not required. In order to provide room for expansion at these joints, the existing concrete surface was coated with about $\frac{1}{2}$-in. layer of an asphaltic fiber cement. This provided a cushion, which could be compressed by the expanding concrete and would prevent spalling of the concrete edges or displacing of the sections due to temperature changes. At vertical construction joints in the walls subjected to water pressure, a copper strip—attached at its lower end to the horizontal copper strip in the foundation—served as a water-stop, and provisions, the same as previously outlined, were made to take care of temperature changes.

Only a few sections of the finished floor in Basin No. 1 and even less in Basin No. 2 had been completed, when concreting was stopped for the winter

of 1923-24. The remainder of the year 1923, as well as the first few months of 1924, were used in completing the excavation of the depressed part of Basin No. 1, as well as the depressed parts of the other three basins. This excavated material was loaded on standard gauge dump cars and placed in a railroad fill some distance from the site of the work.

Early in the spring of 1924, the contractor started making forms for the columns and for the groined arch roof of the basins. (See Fig. 15.) For the sections for the arched roof 596 forms were made, or enough to permit pouring the arches over 149 columns at one time. This required the use of each form on an average of seven times during the course of the work.

Concreting in the groined arch roof was commenced in Basin No. 1 on April 26, 1924. The columns were poured for the full height in one operation, and then, before commencing on the arches, a sufficient time was allowed to elapse to permit the concrete in the column forms to shrink. The arches were poured in groups of four, and usually three of these groups were completed in one pouring, making a double row of arches from one barrel arch to the next. Column and arch forms were left in place 14 days in the spring and 10 days in the hot summer weather. The arches were partly loaded after 21 days.

On November 1, 1924, the work in Basin No. 4 had been completed as far south as the running track in front of the tail-tower. The tail-tower tracks were then removed from the easterly half of this basin and construction work in this area carried on by means of a 35-ton locomotive crane, operating from the running track in front of the tail-tower tracks, and also from the track just outside the south wall. As soon as the eastern half of this end of the basin had been completed, the remaining tail-tower tracks in this basin were removed and operations carried on by a locomotive crane, the same as for the eastern half of the basin. In this same manner the other basins were completed until the eastward travel of the cableway was stopped at the westerly side of Gate-House No. 1.

## Filters and Effluent Galleries

*Excavation.*—The general excavation of the Administration and Filter Building site was included with the excavation for the coagulation basins, for which bids were received April 29, 1920. Delay by the City in acquiring the land on which these structures were to be located prevented the immediate excavation, and the work was assigned to the contractor having the general construction of Baldwin Reservoir. Excavation of this site was begun in the late summer of 1923.

*Construction.*—On October 24, 1923, bids were received for the construction of the Administration and Filter Building, and the contract was awarded to the low bidder, who was already engaged in constructing the coagulation basins.

By extending the cableway tracks west (Fig. 14) for the full length of the filter building, the same plant could be used as for the coagulation basins. The contractor immediately began excavating the 12-in. cover left on the foundation bed and prosecuted the work so vigorously that, when con-

crete operations were suspended near the end of December, 1923, the concrete floor-slab for the southeast effluent gallery, as well as two-thirds of the walls around this same section, were completed.

During the remainder of the winter, the excavation of the main drain was completed. The material encountered was composed of layers of a hard, fine-grained sandstone, between which were thin layers of hard shale. The sides of the main drain were cut with a channeling machine, and the lateral connections, located at every filter, were cut by drilling closely spaced holes, with jack-hammers.

Concreting was resumed early in the spring of 1924. The roof-slab over each effluent gallery was poured in five sections. The construction joints were placed at the dividing plane between the double beams located at the end of every second filter. Due to the length of time required in pouring each roof section of the effluent gallery and the great amount of beam steel located just above the columns, it was found best to pour all the columns in any one section as soon as the column and beam forms were completed, but before the beam and slab steel had been placed. The columns were poured up to the under side of the deepest beam supported by that column. Before placing the forms and concreting the last roof section in each gallery, all the pipe and fittings for the collector system were lowered into the gallery.

Each of the concrete filter tanks (Fig. 16), including the floor, walls, and top walks, was constructed in one operation. Seven sets of forms, and four additional sets, complete except for the outside forms for the two side walls, were prepared. This permitted work on eleven filter tanks at one time, as each of the four sets of forms lacking the outside wall forms, could be used between two filter tanks already poured and stripped.

Each filter tank was poured as a monolith, and the first step was to pour the floor. This served to hold the mortar in the concrete in the side walls and prevented its escape under the lower edge of the inner supported wall form.

The quantity of concrete in one filter tank was 156 cu. yd. The time required to concrete one filter ranged from 3¼ to 5 hours, the general average being a little more than 4 hours. The first filter was concreted on May 12, and the last one on August 29, 1924.

### Chemical House and Mixing Flumes

Bids for constructing the chemical house and mixing flumes were received on July 23, 1924. These were rejected, the work was re-advertised, and new bids were received on August 20. The contract was awarded to the contractor already engaged in building the remainder of the plant.

Because the site of the work was partly covered by the existing cableway tail-tower tracks, it was necessary to restrict the westerly movement of the cableway to a point about midway of the work under this contract. The cableway tracks were then removed west of this point and excavation for the chemical house was begun.

Standard-gauge railroad tracks were laid along either side of the building site and locomotive cranes operating on these tracks were used to hoist

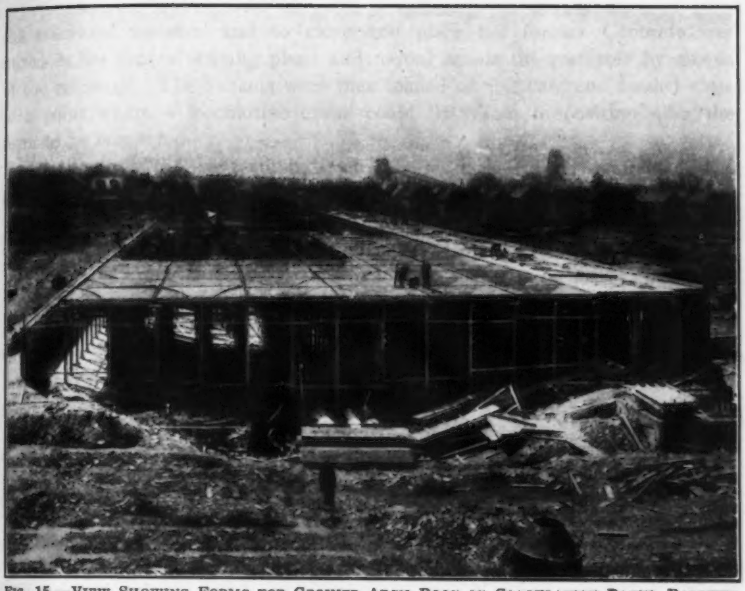

FIG. 15.—VIEW SHOWING FORMS FOR GROINED ARCH ROOF OF COAGULATION BASIN, BALDWIN FILTRATION PLANT.

FIG. 16.—PIPE GALLERY AND FILTER TANKS DURING CONSTRUCTION, BALDWIN FILTRATION PLANT.

the excavated material and to move and place the forms. Concrete was mixed in the central mixing plant and moved across the reservoir by means of the cableway. The buckets were then loaded on flat cars and hauled close to a point where a locomotive crane could lift them to position over the form to be concreted.

By the time the westerly half of this work had been completed, the cableway was dismantled and a track was laid from the mixing plant around the east and south sides of the coagulation basins to connect with the working track on the south side of the chemical house. Concrete for the remainder of this work was brought from the central mixing plant by means of this track. The dissolving and solution tanks, as well as the small orifice boxes, were each poured in one operation up to a construction joint above the level to which they would be filled. This eliminated the possibility of leakage, which might have occurred, had there been a construction joint where the wall and floor joined.

To guard against the disintegration of concrete in the tanks to be used for alum solution, a richer mixture was used in order to obtain as dense a concrete as possible. For the dissolving and solution tanks, with 12-in. walls, concrete proportions of approximately 1:1.5:3 were used, and for the orifice tanks, with walls 6 in. thick, a mixture of approximately 1:1.25:2.5 was used. In addition, the interior surfaces of all these tanks were coated with a special acid-resisting paint.

## Filter Equipment

Bids for filter equipment, received on June 12, 1924, were rejected, and the work was re-advertised as a separate part of the chemical house contract. New bids were received on July 23, 1924, and the work was awarded to the low bidder, who immediately started manufacturing the equipment.

The cast-iron manifolds and laterals, as well as the effluent piping and rate controllers, were delivered to the site of the work in railroad cars. Delivery of the rate controllers, as well as of the filter manifolds, was started on October 8, 1924.

By January 30, 1925, the superstructure over the filters and operating gallery had so nearly reached completion that the contractor for the filter equipment was permitted to start placing the filter rate controllers. On February 10, the first manifolds were placed in position in the filters.

The large number of filters and the repetition of the same steps at each filter permitted doing the work in a very rapid and efficient manner. It was subdivided into different operations, each of which was performed by a separate crew. As an instance of this subdivision, the work inside the filters may be cited. One crew confined its efforts to placing in position and bolting down the manifolds, and then moving on to the next filter as soon as this operation was finished. Another crew followed and drilled the holes in the floor by means of which the lateral chairs were anchored in position. The drillers were followed by a crew which placed the laterals and chairs in position, and this work was followed by the various operations, such as pour-

ing the lead joints, caulking joints, placing brass strainers on the manifolds, placing the various layers of gravel, and, finally, placing the filter sand.

The filter gravel and sand were purchased by contract. The first bids were rejected and new bids were received November 6, 1924. The coarse filter gravel, ranging from 1½ in. to ¾ in. in size, was obtained from the Ohio River, near East Liverpool. The gravel ranging from ¾ to ¼ in. in size, a part of that ranging from ¼ to ⅛ in. in size, as well as part of the gravel ranging from ⅛ to 1/16 in. in size, was obtained from Copley, Ohio. The remainder, as well as the filter sand, came from Phalanx, Ohio.

All gravel and sand was received in railroad cars on tracks laid close to the filter building. The three larger sizes of gravel were unloaded by shoveling on to a belt conveyor, which carried it inside the building and dumped it into a hopper from which it could be drawn into wheel-barrows. The smallest size of gravel, that from ⅛ to 1/16 in., and all the sand were unloaded directly from box cars into the filters by means of ejectors placed in the cars.

The following approximate quantities will give some idea of the amount of work involved in constructing the Baldwin Filtration Plant:

| | |
|---|---|
| Excavation, in cubic yards | 1 100 000 |
| Fill, in cubic yards | 290 000 |
| Concrete, in cubic yards | 185 000 |
| Barrels of cement used | 290 000 |
| Brick | 2 300 000 |
| Cut stone, in cubic feet | 102 000 |
| Reinforcing steel, in pounds | 10 900 000 |
| Structural and miscellaneous steel, in pounds | 3 000 000 |
| Cast-iron pipe and fittings, in pounds | 8 000 000 |
| Filter sand, in cubic yards | 5 400 |
| Filter gravel, in cubic yards | 3 500 |

These quantities do not include work on the alum storage building, the Fairmount Control Works, the pipe lines leading to the filter plant, nor the pipe lines leading from Gate-House No. 7, that connect into the distribution system. Fig. 17 is a panoramic view of the finished plant.

## General Equipment

The equipment of the Baldwin Filtration Plant is best described under six main divisions: The alum storage plant, chemical house, administration and filter building, and lighting, heating, and telephone systems.

*Alum Storage Plant.*—To facilitate the unloading of alum from the box cars in which it is received, a power shovel or car plow, operated by a 5-h.p. motor at 1 200 rev. per min., is provided. The alum received from the car passes through a chute to an apron feeder conveyor driven by a 2-h.p. motor at 1 200 rev. per min. This conveyor can deliver the alum either to a 24 by 20-in. rigid hammer crusher, operated by a 20-h.p. motor at 900 rev. per min., or directly to a pivoted bucket carrier. The crusher has a capacity of 20 tons per hour, when crushing 5-in. lump alum to approximately ½-in. pieces.

The alum is lifted to the top floor of the building by a pivoted bucket carrier traveling at the rate of 40 ft. per min., and driven by a 5-h.p. motor at 1 200 rev. per min. The buckets are 18 by 15 in. and, after moving

FIG. 17.—VIEW OF BALDWIN FILTRATION PLANT.

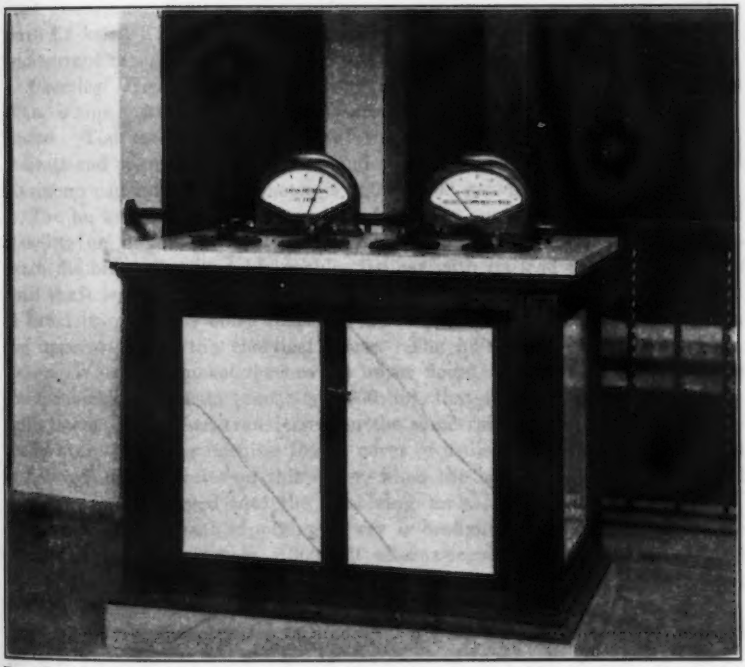

FIG. 18.—ONE OF THE BRONZE AND MARBLE FILTER OPERATING TABLES, BALDWIN FILTRATION PLANT.

horizontally with their load of alum, rise vertically to the upper floor, where they may feed any one of three 12-in. screw conveyors. These latter, each of which is 64 ft. in length, deliver the alum to the various bins through gated chutes. The screw conveyors are driven through friction clutches and bevel gears by a 7.5-h.p. motor at 1 200 rev. per min.

A dust collector system and filter is provided for the collection and filtration of the dusty air produced in handling the alum. A 5-h.p. motor at 1 200 rev. per min. operates the fan used for sucking the dust-laden air from the crusher, chutes, and rooms where it is produced, and for forcing it through the cloth filter.

The building is provided with a platform elevator, 5 ft. square, with a capacity of 2 500 lb. when moving at a speed of 150 ft. per min. A 13-h.p. motor at 900 rev. per min. is used for operating the elevator.

Electric current for operating the motors is 3-phase, 60-cycle, alternating current at 2 300 volts, which is reduced to 220 volts through three 15 kv-a transformers. A remote-control panel board with switches for operating the car plow, crusher, bucket carrier, screw conveyors, etc., is placed outside the room containing the power transformers. This same room also contains three 1.5 kv-a., 2 300 to 110-volt transformers for the lighting system. Electric current is supplied from generators in the Fairmount Pumping Station.

*Chemical House.*—The raw water entering this building through two 60-in. mains, passes through two Venturi tubes with throats 30 in. in diameter. The rate and total flow of water are shown on two meters, that indicate and record the rate of flow and also register the total flow. The rated maximum capacity of each meter is 120 000 000 gal. per day.

The bucket used to lift the alum from the storage bins, is filled while standing on a flat car, which runs on a narrow-gauge (24-in.) track beneath the bins. A turn-table enables the car with its load to be run into the hoist shaft leading to the top floor of the chemical house. The loaded bucket is lifted by a geared hoist (capacity 3 000 lb.) mounted on a mono-rail in the upper story of the chemical house. The hoist is operated by a 3-h.p. motor. When the bucket reaches the upper floors, it is moved by hand along the mono-rail to a scale (capacity 4 000 lb.), that forms a part of the mono-rail system. It is then transferred on the same rail system to a position directly over a circular opening in the cover of a dissolving tank. The bucket is lowered until it rests on this cover, when the bottom gate is opened, and the alum is discharged into the dissolving tank.

The electric current supplying power is brought into the building in the form of a 3-phase, 60-cycle, 2 300-volt alternating current, which is reduced to 220 volts through three 10 kv-a. transformers. Three 5 kv-a. transformers are also used to convert the 2 300-volt current to 110 volts for lighting purposes. The transformers are located in a separate room especially provided for this purpose.

The electric passenger elevator, in addition to being a convenience for the operating force, may serve as a means of carrying alum up from the bins to the dissolving tanks should the bucket hoist fail to operate. It has a lift of 56 ft., a capacity of 2 500 lb., and a maximum hoist speed of 150 ft.

per min., under full load. The shaft in which it operates is 6 ft. by 6 ft. 6 in. in plan. The elevator is driven by a 13-h.p. motor operating at 900 rev. per min.

The dust-collecting system consists of seven hoods, one over each possible loading position of the bucket. It also includes collector piping and valves and a dust arrester with a discharge hopper and outlet equipped with a dust valve and canvas spout. The fan is driven by a 10-h.p. electric motor running at 1 160 rev. per min.

The tanks for dissolving sulfate of alumina are each 6 ft. 6 in. by 5 ft. in plan and have a depth of 6 ft. 9 in. There is a 3-in. ledge 1 ft. above the bottom, which supports a wooden grid. This, in turn, supports a removable acid bronze screen upon which the alum is dumped. Below the bottom of the wooden grid, is a lead pipe distribution system for furnishing the dissolving water. In a recess at the end of the dissolving tank is a wooden baffle in line with the concrete wall below. Beyond that is an acid bronze screen, designed to remove trash of all kinds from the solution before it passes into the storage tanks. The wooden grid is made in three sections and is composed of 1⅝-in. by 3⅝-in. cypress joists set on edge with ¾-in. spacer blocks between the joists. The joists of each section are bolted together with ¼-in. bolts painted with an acid-proof paint before assembling. The bronze screens are set in cypress frames, and are composed of acid-proof bronze wire, 0.08 in. in diameter, 4 meshes per in. for the strainer screen and 6 meshes per in. for the screen resting on the wooden grid. These dissolving tanks were designed for a maximum charge of 4 000 lb. of chemicals.

Each solution storage tank is 15 ft. 4½ in. by 18 ft. 3 in. in plan, with an average depth of approximately 10 ft. The bottom of the tank slopes 1 ft. 6 in. in its length, with a drain at the low point. The solution outlet from the tank is 19 in. above the drain. This design was adopted to form a sump into which trash or separated aluminum hydrate might settle and not be carried into the chemical pipe lines. To effect a mixing action in the solution tanks by driving water up through a grid at the bottom and supplying make-up water for bringing the solution to a predetermined strength, four 1½-in. lead pipes spaced equi-distant across the bottom of the solution tank and tied into a 2-in. header are provided and are supplied with water through a 2-in. feed line. The four 1½-in. laterals in the bottom of the tank are each provided with ¼-in. holes on 3-in. centers drilled in the top of the pipe.

Each orifice box is 1 ft. 9 in. by 4 ft. in plan and 3 ft. 9 in. deep, with the center line of the orifice set 1 ft. 11 in. above the bottom. Each box is divided into two compartments by a wooden baffle. Into one of the compartments the alum solution is discharged and passes over the baffle into the second compartment. The baffle acts to still the disturbance produced by the discharge of the solution. The float for maintaining a constant head over the orifice is placed in the second compartment. The orifice itself is placed in the wall of the box forming one end of this compartment.

The orifice boxes are designed in pairs with a common dividing wall. As the solution from either orifice leaves this box it passes into a common make-

up box, 18 in. wide, extending across the full width of the two orifice boxes. A 1-in. water line, discharging into this make-up box, permits an increase in the volume of solution which assists in better distribution as it is fed into the water.

The orifice itself has a fixed width of ¾ in. and is capable of being varied from a minimum length of 2½ in. to a maximum of 7 in. The orifice plate is made of acid bronze and consists of a base plate set in the concrete to which the orifice plate proper is attached. One end of the orifice is designed to remain stationary while the other end is moved by a screw operated by a hand wheel. A pointer on the movable part of the plate indicates the opening on a scale set below.

For conveying the alum solution from the orifice boxes, a pipe leads from each set to a distributing trough over the rising well. This is a wooden trough, 70 ft. long, covered with sheet lead ⅜ in. thick, and hung from bolts fastened to inserts placed in the concrete floor above.

The joints of the lead sheets are burned together, and on the down-stream side of the trough lead lips are spaced 2 ft. 6 in. apart. The trough is V-shaped, with a bottom angle of 90 degrees. It is 18 in. wide across the top and has a depth of 7 in. above the top of the fillet.

In order to obtain a uniform discharge of the solution from each lip, the level of the trough may be accurately adjusted by turnbuckles.

*Administration and Filter Building.*—There are four wash-water pumps on the floor at Elevation 216.0 for lifting the water from the effluent galleries to the wash-water tanks, in the top story of the Administration Building. They are operated through electric control actuated by means of floats in the wash-water tanks. The float contacts are arranged so that if the level of the water in the tanks continues to drop, additional pumps are thrown successively into service. The electric control panels are in the pump-room adjacent to the pumps. Push-button control is also provided in the pump-room. Two pumps, each with a capacity of 3 450 gal. per min., are driven by 75-h.p., induction motors of the squirrel-cage type, running at 1 760 rev. per min. Each of the other two pumps has a capacity of 1 850 gal. per min. and is driven by a 40-h.p. motor of the same type, running at a speed of 1 750 rev. per min. The current used in the motors for these pumps is a 3-phase, 60-cycle, at a potential of 2 300 volts.

Electric power for operating the motors on these pumps is obtained from two sources: From cables of the Municipal Electric Light Plant; and from the generators at the Fairmount Pumping Station.

The transformer and switchboard room contains the four primary control panels for the four wash-water pumps; three 25-kv-a. transformers for converting the current from 2 300 volts to 220 volts, for general power purposes other than that required for the wash-water pumps; and three 25 kv-a. light transformers for changing the voltage from 2 300 volts to 110 volts for lighting purposes.

The large freight elevator (7 by 6½ ft.) serving all floors in the Administration Building, has a capacity of 10 000 lb. at a speed 75 ft. per min. The power is obtained from a 27-h.p. electric motor, operating at 900 rev.

per min. The machine shop is wired for machine tools, and a switchboard control panel has been installed.

In the foremen's room on the main floor of the Administration Building is located the wash-water Venturi meter register. The Venturi tube is 24 in. in diameter, with a 14-in. throat.

In this same room are two indicating depth gauges, one for each basin of the Baldwin Reservoir, and one pressure gauge to indicate the depth of water in the wash-water tanks. A high-water electric alarm bell notifies the operator when too high a level is reached in the wash-water tanks.

The chlorine room on the floor at Elevation 234.0 is located with one wall just beyond the outlet end of the filtered water conduit at Elevation 216.0. A pit, 1 ft. 6 in. by 3 ft. 6 in., and 2 ft. 3 in. deep, is built into the floor of this room. Passing through the wall of the pit are three 2½-in. galvanized-iron pipes, 7 ft. 6 in. long, and extending from 6 in. inside the pit wall to a point over the center line of the outlet end of the filtered water conduit. A manhole is located in the floor at Elevation 234.0, just over the end of these pipes. A heavy rubber hose fed by the chlorine machines may be placed in each pipe with its outlet end submerged in the water of the effluent channel leading to the clear-water reservoir.

For feeding the chlorine, there are two control units each with a maximum capacity of 320 lb. per day. The room in which these machines are located, is equipped with two vestibule entrances, each having two sets of double doors to prevent the spreading of fumes to other parts of the building. A ventilating system is also provided for exhausting the fumes from the chlorine room proper. The exhaust fan is located on the wash-water tank-room floor, and is driven by a 5-h.p. motor operating at 900 rev. per min.

An operating table is provided for each filter tank (Fig. 18). It consists of an ornamental cast bronze frame with statuary finish and with Tennessee marble panels and top. On the top are four levers equipped with indicators. These levers are used for opening and closing four-way cocks which admit and release water under pressure to the hydraulic cylinders used to open and shut the influent, effluent, sewer, and wash-water valves. A shut-off valve for the pressure manifold, and bronze casings for holding the loss of head and rate-of-flow gauge mechanisms, are also placed on the top of the table. In the hood of each gauge is a small electric bulb for illuminating the face of the gauge at night. The marble panels at the back of the table are omitted, the opening being closed, however, by a brass wire screen for ventilating purposes. The operating tables and fixtures were especially designed for this plant.

The 8-in. pressure supply line for operating the hydraulic valves is under a pressure of 150 lb. per sq. in. As this is too high for this purpose, it is reduced by an 8-in. pressure-regulating valve to about 110 lb. per sq. in. All waste lines from the four-way cocks discharge into the main gutter of the filter.

The effluent valve of each filter is placed down stream from the rate controller and this permits each controller to be emptied for inspection or re-

pair without draining the effluent galleries. This arrangement, however, subjects the controller and connected mercury pots to the full head of the wash-water pressure. This necessitates the cutting off of wash-water pressures, during the washing process, from the mercury pots for the rate of flow and loss of head gauges. The effluent valve, therefore, when closing, automatically closes two small hydraulic valves in the small pressure pipe lines leading from the controller to the mercury pots. These devices prevent the mercury from being forced out of the pots while the controller is under pressure in the washing process. These cut-off valves open automatically when the effluent valve is again opened.

*Lighting.*—A very complete system of lighting has been installed in all the buildings. Special lighting for the filter tanks enables operators to view the filtering and washing processes at night. The offices and laboratories are extremely well lighted. Ornamental fixtures and lights are installed in the end and cross pavilions of the wings of the filter building.

*Heating.*—A low-pressure (5-lb. gauge and 10-in. vacuum) vacuum type of steam heating is provided for all the buildings except the gate-houses. Thermostatic control is used in the Administration Building. Steam is supplied from the boiler plant at the Fairmount Pumping Station.

*Telephone System.*—A 24-station intercommunicating telephone system furnishes contact between the offices, laboratories, foremen's rooms, and other important points in the plant. Duplicate sets of talking and ringing batteries are located in the machine shop, and are kept constantly charged by a motor generator set.

## Completion of Baldwin Filtration Plant

The construction of the Baldwin Filtration Plant and Reservoir, as well as of all allied projects necessary to make the operation of this plant possible, was hastened in every way, in order to derive the benefit of increased pressures in the low-service district due to the use of the new reservoir.

All the various projects had been so nearly completed, that in June, 1925, it was possible to test and clean out the regular water channels in the Baldwin Filtration Plant from the chemical house through the filtered-water by-pass in the Administration Building, to Baldwin Reservoir. On June 29, 1925, raw chlorinated water was first passed through the previously mentioned water channels into Baldwin Reservoir and on July 1, 1925, this reservoir was connected to the low-service distribution system.

From the average results of twenty-two gauging stations, throughout the low-service district, the increased pressure due to the change to the higher reservoir was 16.6 lb. This was the difference between the average of the readings at 9:00 A. M., before cutting in the new reservoir, and that at 2:30 P. M., after the system had been changed over. This increase in pressure was obtained with the water in Baldwin Reservoir about 7½ ft. below the overflow.

The placing of the filter equipment progressed so satisfactorily that on September 15, 1925, the filtered-water by-pass was closed and the first chemi-

cally treated water was passed through the coagulation basins and to the west twenty filters, thus placing one-half the plant in service. On October 20, the remaining filters were available for service.

The total elapsed time required for the construction of the plant was slightly more than three years and eleven months. This is computed from the date of awarding the contract under which the reservoir was constructed, to the date on which all the filters were ready for service, and the plant was ready for output of its full capacity. It excludes the time required for the excavation of the reservoir and coagulation basins.

## Amounts of Contracts and Analysis of Costs

The various items entering into the cost of Baldwin Filtration Plant are given in Tables 2 and 3. In preparing this detailed statement, the actual cost of the asset is given; this cost is also adjusted to a base cost in accordance with the purchasing value of the 1913 dollar. This was done in order to permit cost comparisons on the basis of pre-war values. The cost index figures as prepared by the *Engineering News-Record*, were used in making this adjustment. A comparison of unit costs may readily be made by means of Table 2. For example, the alum storage building, with a capacity of 1 000 tons, cost $132 per ton for storage. On the 1913 basis, the cost is $63 per ton of storage. Similarly, the four coagulation basins, with a total capacity of 32 800 000 gal., cost $49 425 per 1 000 000 gal. The capacity of Baldwin Reservoir is 135 000 000 gal., and its cost is seen to be $21 458 for each 1 000 000 gal. of storage.

Table 3 gives a summary of costs of the units comprising the filter plant proper, including both actual and 1913 values. It also gives for each of these values the cost of each unit per 1 000 000 gal. daily of capacity. This table excludes from consideration, the following items: (1) Mains delivering raw water to the rising well at the chemical house; (2) mains that take water away from outlet Gate-House No. 7; (3) changes at Fairmount Reservoir; (4) landscape development; (5) cost of all land; and (6) rough grading of the filter plant grounds, engineering, inspection, and overhead.

The large capacity of the Baldwin Reservoir is due to the fact that it is used as a storage reservoir for the low-service district. As the normal capacity of a filtered-water reservoir for a filtration plant is about 25% of the normal daily rated capacity of the plant, it is not proper to charge the entire cost of the Baldwin Reservoir to the filtration plant. Accordingly, while Table 3 includes costs for the plant as actually constructed, data are also included for the purpose of comparison, giving costs on the basis of the customary size of a filtered-water reservoir.

A capacity of 40 000 000 gal. would be sufficient for a plant of this size. The exact cost of this smaller reservoir could only be obtained by receiving bids based on an actual design, but for the purpose of comparison it will be assumed that the cost of the smaller, theoretical reservoir would be $\frac{40}{135}$ of the cost of the reservoir as actually built. The totals of Items A, B, C, D, and F, as given in Table 3, represent these adjusted values.

TABLE 2.—DETAILED COSTS OF BALDWIN FILTRATION PLANT.

| Units constructed. | Actual cost of asset. | Cost reduced to 1913 basis by use of cost index figures. | Date of receipt of bids. | Cost index based on the year 1913 as 100. |
|---|---|---|---|---|
| Control Works at Fairmount Reservoir: Substructure: | | | | |
| Contract 18, Foundations of four gate-houses, shafts, branch and main tunnels to header at pumping station, distributing pipe into reservoir, and all sluice-gates | $ 209 891.76 | $ 109 318.63 | January 12, 1923 | 192 |
| Contract 41, Guniting areas, concrete floor of reservoir, and slope wall paving around new openings made in floor and slope walls | 4 548.78 | 2 125.60 | April 13, 1923 | 214 |
| Total, substructure | $ 214 440.54 | $ 111 444.23 | | ... |

## ACKNOWLEDGMENT

As this project has covered a considerable period of time, the work was carried on under four different City Administrations and great credit is due to the City's officials and Councils for their continued support in carrying the project to a successful completion.

The work has been conducted under the general supervision of the Directors of Public Utilities, Messrs. C. W. Stage, Thomas S. Farrell, A. B. Roberts, E. L. Myers, and Howell Wright, and Commissioners of Water, Messrs. C. F. Shultz, J. T. Martin, A. V. Ruggles, and C. P. Jaeger. During the entire development and construction of this project J. W. Ellms M. Am. Soc. C. E., was Engineer of Water Purification and Messrs. A. V. Ruggles and A. G. Levy, Members, Am. Soc. C. E., were Engineers of Construction and Survey. The Frazier-Sheal Company with J. E. A. Linders, M. Am. Soc. C. E., as Engineer of Design, and H. T. Hammer as Resident Engineer, had charge of the design and construction of Baldwin Reservoir. The design and construction of the remaining part of the project was handled directly by the Engineering Department of the Division of Water with A. G. Levy and G. W. Hamlin, Members Am. Soc. C. E., as Engineers of Design and the latter as Resident Engineer. Herman Kregelius, City Architect, designed all the superstructures in connection with this project.

The plant was completed and put into operation under the administration of City Manager W. R. Hopkins and Director of Public Utilities Howell Wright, to whose energy and ability the early completion of the project was largely due.

## CONCLUSIONS

The project involved an expenditure of approximately $10 000 000, and contains engineering features which should be of interest to all those en-

gaged in the design and construction of works of this type. The descriptions are in considerable detail in order to enable other engineers to grasp the essentials of the design and construction and to indicate the magnitude of the work. Certain features like the hydraulic-jump mixing flumes are a departure from the old methods of mixing chemical solutions with the water to be treated; the design of the coagulation basins in providing a straight flow through them with no baffles is an improvement which has proved entirely satisfactory in practice and which is a departure from existing methods; and the use of the sharply sloping floor in the coagulation basins for the dual purpose of reducing the height of the outside walls and facilitating the cleaning of the basins is of practical importance.

The design and construction of Baldwin Reservoir on account of its size, should be of considerable interest to engineers, since it is the largest covered concrete reservoir that was ever constructed. The methods of introducing the water to the reservoir and drawing it off in order to provide good circulation is a point of interest. The groined arches used for the roof have the longest span constructed to date.

The very complete tables of costs are so rarely found in engineering literature that the figures given should be particularly valuable since they represent the careful analysis of all the contracts involved in the project.

The plant is adjacent to the Park System of the city and a proper architectural treatment was essential. The buildings present a most imposing appearance and the beauty of the design as a whole has been rarely, if ever, equalled.

## DISCUSSION

S. M. VAN LOAN,[9] M. AM. SOC. C. E. (by letter).—This paper has been written in a most interesting manner and the description of the plant, together with the tabulated costs, is of high value to all construction engineers.

The writer has been impressed by the structural beauty of the exterior and interior of the Baldwin Filtration Plant. During a visit in 1926, his interest centered upon the influent to the coagulating basins. At the time, the hydraulic-jump mixing flume was under operation. It would be interesting to know whether this installation has given the results which were hoped for and which were expected, and if it bears out in actual operation the expectations that were forecast by the experimental flume.

In June, 1926, the filter beds were operating under a burden of organic growth, and numerous cyclops were noticed on the sand where water was below the surface. Has much trouble been experienced in the operation of the beds due to the organic growth in the applied water? Have taste-producing substances been injected into the lake water so as to contribute either a taste or an odor to the influent of the Filtration Plant, and, if so, what chemical applications have been made for their reduction or elimination? Information has reached the writer indirectly that experiments with ammonia have been made in Cleveland, and it would be of interest to know how far this research work has been carried and what assumptions have been noted.

A reply to these operating questions will be of great value to the filter plant operator regardless of the type of plant on which he may be engaged.

HARRY N. JENKS,[10] M. AM. SOC. C. E. (by letter).—The authors have placed the Sanitary Engineering Profession greatly in their debt for the wealth of technical data and interpretative comment which they have furnished. In discussing a paper of such scope, one is naturally inclined to limit one's self to a consideration of certain specific topics, because only those intimately acquainted with the design conditions and requirements are in a position adequately to evaluate the merits of the conception of the filtration project as a whole.

Following the order of presentation found in the paper, it is significant to note the prominence given the hydraulic data and the influence that hydraulic values have on the satisfactory operation of the plant itself. In particular, the proper control of velocities of flow throughout the plant is considered of great importance to the success of each stage of the process.

One of the most important elements in successful coagulation is the provision of adequate mixing velocities, and the subsequent preservation of the floc, so essential to satisfactory sedimentation.[11] A distinguishing feature of the mixing stage in the Baldwin Filtration Plant is the hydraulic-jump flume installation. The value of this initial rapid mixing is rightly becoming more generally recognized. The writer has obtained excellent results in coagulation by passing the water through an aeration system with a small

[9] Deputy Chf., Bureau of Water, Philadelphia, Pa.

[10] Cons. San. Engr., Berkeley, Calif.

[11] "Elements of Successful Coagulation and Filtration," *Water Works*, Vol. LXVII, No. 5 (1928).

dose of alum to produce a pin-point floc. Thorough coagulation ensued rapidly thereafter when the remainder of the total dose of alum was added. Under these circumstances, also, the aerators served the useful purpose of dissipating the quota of carbon dioxide resulting from the application of the initial dose of coagulant.

From Table 1 it is noted that the observed loss of head through the flume is 2.40 ft. This is in favorable comparison with that encountered in baffled basins or channels for an equal degree of mixing. From the basic data submitted, it is seen that the velocity of the water in the flume is 12.5 ft. per sec. The initial mixing period is, therefore, at most only a matter of a few seconds. The question one might raise is whether full returns for the loss of head of 2.40 ft. are obtained under this time limitation. It seems that a more commensurate initial jarring of the water might be obtained through mechanical mixing. The flume, however, is a very compact device and one that requires no operating attention. Would it not also be possible to construct it so as to make it a means of measuring the flow, in the manner of the Parshall flume?

The use of mechanical mixing devices is deservedly gaining favor among designing engineers and operators of water treatment plants. It is generally desirable to provide for decreasing mixing velocities, which may be obtained through the use of stirring mechanisms operated at corresponding variable speeds. In one of his installations the writer introduced an original design which he has termed "spirovortex" mixing, wherein a controllable mixing velocity is maintained in the coagulation tanks by means of the recirculation of a part of the flow by pumping. Results of experiments indicate the desirability in some cases of providing for chemical agitation as distinguished from mixing as such, to which the "stream-flow" method of recirculation over a riffled surface is particularly well adapted. This in effect involves a series of small hydraulic jumps.

Intermediate between the well-ordered mixing of coagulation and the semi-quiescence of sedimentation, a period of very gentle stirring or streaming should be interposed to produce agglomeration of the floc. This takes place at velocities ranging, for typical waters, from 0.1 to 0.15 ft. per sec. The tank or channel capacity required for this period is more than offset by the resulting possible decrease in the size of the sedimentation basin.

It is significant to note the authors' care in providing for sufficiently low velocities in the coagulated water channels to prevent the destruction of the floc. It is true that an endeavor should be made to keep the velocities within the range of 1.5 to 2.0 ft. per sec. The writer is inclined to the belief, however, that it is not so much the specific velocity as the character of the flow itself, which is the governing factor. It seems that the floc may be unharmed even if considerably higher velocities are present, provided the flow is smooth and free from excessive eddies. Abrupt changes in direction, causing impact, represent the most unfavorable conditions. Furthermore, the entrainment of air, or the agitation of the water by air, is conducive to the destruction of the large flocs, and their re-solution into a colloidal state. In general, channels and gate openings which have good hydraulic conditions involving low hydraulic losses are favorable to the preservation of the floc, especially if

the hydraulic radius of the channel is large, thus inducing a relatively small amount of "drag" on the side walls in comparison with the volume of flow.

From Table 1 one may note the close agreement between the computed and observed loss of head through the pre-treatment portion of the Baldwin Filtration Plant. Such information should be of value to designers in making an appropriate allowance for such loss. In this connection Fig. 19 will be of interest. This is a balanced curve and is drawn through the plotted points of observed losses of head. The nominal design of capacity of the plant to which this curve refers, was 32 000 000 gal. per day, a rate at which the total loss of head is seen to be 1.8 ft., increasing to 5.0 ft. at the designed maximum flow of 48 000 000 gal. per day.

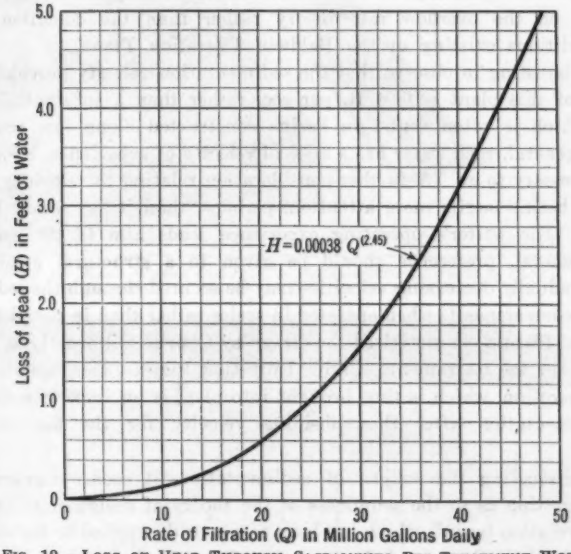

FIG. 19.—LOSS OF HEAD THROUGH SACRAMENTO PRE-TREATMENT WORKS, BETWEEN COAGULATION TANK NO. 1 AND THE FILTERS.

During recent years it has become apparent to sewage works engineers that optimum conditions for sedimentation are more dependent on basin area than on crude detention period. Advantage is now being taken of the important influence of the area factor in the design of relatively economical, shallow basins for water filtration plants, the basins being provided with continuous sludge removal. Current investigations by the writer indicate that hydraulic means for the satisfactory removal of the sludge may be applied on a large scale.

The authors' data show that the following significant factors entered into the design of the Cleveland coagulation basins:

| | |
|---|---|
| Total net settling area (inside of basins), in square feet | 283 200 |
| Average depth of water, in feet | 15 |
| Velocity of flow, in feet per second (at 2.36 ft. per min.) | 0.04 |
| Detention period, in hours | 4.7 |

Based on a flow of 165 000 000 gal. per day, or 114 500 gal. per min., the area allowed for sedimentation equals 2.47 sq. ft. per gal. per min., which is a high enough value for this factor to account for the excellent sedimentation efficiency found at the Baldwin Plant. Since the volume of flow is 917 000 cu. ft. per hour, the conditions of operation permit an overflow rate of 3.25 ft. per hour. This appears to be quite conservative for alum floc.

The 15-ft. depth of water is a large factor in the provision of the 4.7-hour storage period. It would appear possible in many cases to effect a more economical design through fixing the depth factor at, say, 8 ft., and installing means for continuous sludge removal. It would be of value to learn from the authors their opinion as to the relative merits of coagulation basin design predicated on the overflow rate theory rather than the detention period, under conditions existing at the Baldwin Filtration Plant.

It is interesting to observe that the sedimentation velocity provided by the designers of this plant is 0.04 ft. per sec. rather than a substantially lower velocity which is often found in basins constructed along less economical lines. In general, each water has a critical velocity of subsidence, below which it is unnecessary to go. A further consideration relating to velocities of sedimentation basins merits more attention, perhaps, than it has received among designers. The writer's operating experience leads him to the conclusion that, in general, preference should be given to a structural arrangement whereby gradually decreasing velocities may be secured through the sedimentation basin compartments when operated in series rather than in parallel. Such a functional feature characterized the design by Charles Gilman Hyde, M. Am. Soc. C. E., for the Sacramento, Calif., Filtration Plant. The phenomenon of floc agglomeration, which is thus brought into play, is an important factor in rapid sedimentation after the subsiding velocity for the floc is finally attained.

While discussing the subject of sedimentation, it seems appropriate to raise the question as to the soundness of the theory of design implied by the term, "coagulation basin", which has been so generally applied to the structure intended for the settlement of the precipitated matter from the water passing through the basins. It is a matter of considerable surprise to observe the tendency that has prevailed in filtration plant design, involving inadequate chemical mixing and a dependence on the sedimentation basin for the actual completion of the required reactions of coagulation. In the interests of economical design, as well as of economy and flexibility of operation, the stages of coagulation and sedimentation should be complete in themselves, and distinctly separate from each other. When means are provided for thorough coagulation (preferably with agglomeration), it will generally be found that the size of the sedimentation basins as such may be reduced to a degree that will more than compensate the cost of prolongation of the chemical mixing period. Then, with proper inlet and outlet arrangements and with long, narrow basins, similar to those at the Baldwin Plant, it is possible to obtain exceptionally high sedimentation efficiency, as measured by the removal of suspended

solids and the ratio of the flowing-through period to the detention period. The deposition of sludge along the course of flow is also remarkably uniform.

A number of interesting points are raised in the authors' description of the design features pertaining to the filters. The capacity of each filter, amounting to a little more than 4 000 000 gal. per day, is in keeping with the modern tendency toward large-sized units. The design of the filters in detail conforms to the best engineering practice, and several features deserve special notice. Among these is the provision for the adjustment of the height of the wash-water gutters. Much is yet to be learned regarding the most desirable and efficient rates of wash, and size and depth of sand. The possibility of changing the elevation of the gutters enables the operator to meet variable operating requirements, as well as to take advantage of information that may become available in the future as regards the physical functions of the filter itself. At Sacramento, Calif., adjustment is made by bodily raising or lowering the entire gutter, which may be readily accomplished through manipulation of the hanger-bolts shown in Fig. 20. At Fort Dodge, Iowa, the writer provided similar adjustable gutters, primarily with a view to enabling appropriate modifications to be made whenever a change from deep wells to the Des Moines River as a source of supply should become necessary.

The authors describe a strainer system designed in accordance with results of experiments by Mr. Ellms. There are two typical situations of this kind in a filter plant, (1) the wash-water manifold and laterals in a filter; and (2) the header and pipe system for an aeration field. The latter is illustrated in Fig. 21. One of the authors has shown[12] that the hydraulic theory applicable to the design of the filter underdrain system (laterals and perforations) may be used successfully in proportioning manifolds and laterals. The validity of this theory is well attested by the operation of the Sacramento aerators shown in Fig. 22. This view shows an aeration field approximately 172 by 40 ft. in plan. In this case the ratio of the combined areas ($a$) of pipes to the area of the main header ($A$) is, $\frac{a}{A} = 0.41$. The pipe laterals are 10 in. in diameter and 40 ft. long, while the header channel is 12.5 by 4.5 ft. The aggregate areas of the nozzle risers in each lateral are equal to four-tenths the area of the lateral. There are 420 sprays spaced 4 ft. on centers, the discharge from which is uniform at all rates (see Fig. 22).

It is significant of the tendency toward the use of deeper gravel beds that the authors specified 22 in. of graded gravel in the Baldwin Filters. The writer is also in agreement with the use of smaller sizes of rock than has often been furnished. His own experience confirms the wisdom of having a relatively large portion of the total depth comprise rock ranging in size from $\frac{3}{4}$ to $\frac{1}{2}$ in. This adds materially to the stability of the upper gravel layers and is a good safeguard against the intermingling of the overlying sand with the gravel beneath.

In connection with the filter equipment installed at the Baldwin Plant, the provision of only two gauges for each filter, namely, the wash-water and loss-of-head gauges, is in reality all that is required. From the standpoint of economy

[12] *Journal*, Am. Water Works Assoc., Vol. XVIII, December, 1927, p. 664.

durability, and attractiveness, one may regard with favor the development of filter operating tables in the form of electrically-operated panel boards. The first installation of this type was made under the writer's direction at Sacramento,[13] and, subsequently, it was introduced in the water-works design at Fort Dodge, Iowa. Fig. 23 shows the original Sacramento panel board. The provision of electrical indicating instruments obviates the requirement of a specific position of the control panel to fit the location of float-tubes and accessories; also, all actuating strings and rods can be eliminated, particularly on the valve-opening indicators, which are readily actuated by reactance coils responding to the movement of the valve stem followers.

JAMES H. HERRON,[14] M. AM. SOC. C. E. (by letter).—In this paper the excellent compilation of cost data is one of the most valuable features. While the improvement was made during the period of high costs, the proper index can be applied to make them available for any period.

It has been a source of gratification that the plant as finally planned has worked out so well, since both the Cleveland Water Department and the Commission of Engineers, of which the writer was a member, were severely criticized for separating the Filtration Plant from the initial Pumping Station. Difficulty had been experienced with sub-grade conditions at one of the other plants located on the shore of the lake, and it was deemed impossible without high cost to build this plant adjacent to the Pumping Station. Since the Baldwin Reservoir had already been planned as a distributing reservoir for the low service, it was thought wise to avoid the expense of an additional filtered-water reservoir by utilizing one already available. The cost of pumpage is little different whether the water is delivered to the Filtration Plant through long lines and into the reservoir through short lines, or *vice versa*. The separation of the plants may have involved some additional pumping capacity, but with little greater total head. The increased investment was more than offset by the saving effected in utilizing a reservoir already planned and practically built as a clear-water basin.

In the building of the plant the utmost care was taken in the selection and handling of materials. The aggregates especially were approved only after examining all available supplies.

In the concreting operations great care was used in the grading of materials and in the quantity of water. This latter was kept at a minimum. Between 300 and 400 tests were made on concrete cubes (tests on cubes were then required by the Building Department of the City of Cleveland), with the following average results:

| Nominal mix. | Strength at 28 days, in pounds per square inch. |
|---|---|
| 1:3:5 | 2 475 |
| 1:2:4 | 3 100 |
| 1:2.5:3.5 | 3 400 |
| 1:3:3 | 3 875 |

[13] "Electrically-Operated Gages Devised for Filters," *Engineering News-Record*, Vol. 95, No. 9 (1925).

[14] Cons. Engr., Pres., The James H. Herron Co., Cleveland, Ohio.

The higher strength mixes were used for the important work, and the results fully justified the care exercised.

The concreting operations, both as far as the proportions of the materials and placement were concerned, were in advance of the general state of the art then prevailing. As a result the structure has shown no signs of disintegration or other deterioration, and should give continued satisfaction.

E. SHERMAN CHASE,[15] M. AM. SOC. C. E. (by letter).—The writer has been impressed not only by the size of the Baldwin Filtration Plant, but by the general excellence of its design and construction. It is gratifying to have so complete a description of the plant available in permanent form.

The use of the hydraulic jump for bringing about the mixing of the coagulating chemicals with the water is one of the interesting features of the plant. This method has the obvious advantage of simplicity and absence of mechanical equipment. On the other hand, there is a loss of head involved of approximately 2½ ft., which could have been largely avoided had mixing tanks equipped with stirrers been installed. Furthermore, stirring devices capable of being operated at variable speeds permit somewhat greater flexibility of operation than flumes of fixed dimensions.

The application of the aluminum sulfate in solution rather than in the dry form is a departure from what seems to be the present trend in filter plant practice. It is probable, however, that in a large plant with an adequate laboratory staff, the adjustment of the alum dose can be regulated more exactly by the method adopted than by dry feed. Economy in the use of coagulants is of substantial merit where large quantities of water are treated daily.

The adjustable weir plates on the wash-water troughs are novel features and the wisdom of this provision has apparently been substantiated in practice as shown by the experiences described by W. C. Lawrence, Superintendent of Filtration at the Baldwin Plant.[16] According to Mr. Lawrence difficulties in securing proper cleaning of the sand grains during filter washing were overcome by increasing the rates of vertical rise with increased temperatures of the raw water. Had fixed overflow weirs been provided at the lowest elevation available, it would have been difficult to have readily increased the rate of wash without undue loss of sand.

The advantage of high-velocity wash appears to have been shown elsewhere. This is particularly true at the filter plant at Greenwich, Conn., and has been demonstrated experimentally at Detroit, Mich.[17] It seems probable that in the future more liberal provision for high wash-water rates will be made in filter-plant design than has been the general practice in the past.

The characteristics of the filter sand closely follow the usual specifications. Experience in the Greenwich plant indicates that the requirements for a low uniformity coefficient may be unnecessary in the case of rapid sand filters.

[15] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

[16] "Variable Wash Water Rates with Changes of Water Temperatures," *Journal*, Am. Water Works Assoc., Vol. 22, No. 2 (1930).

[17] "Studies on the Washing of Rapid Filters," by Messrs. Hulburt and Herring, *Journal*, Am. Water Works Assoc., Vol. 21, No. 11 (1929).

At this plant, six of eight filters were provided with sand having an effective size of 0.36 to 0.37 mm. and a uniformity coefficient of 1.48 to 1.55, whereas, in two other filters, the sand had an effective size of 0.37 mm. and a uniformity coefficient of 4.65.[18] Operation records have demonstrated equally satisfactory results with the two sands. The reason for equal performance is probably due to the fact that the hydraulic grading of the sand by washing results in the finer sand being brought to the surface of the bed where most of the purification is accomplished.

In closing, it is interesting to note that the City of Cleveland has expended about $7 000 000 for the purification of a supply which, as late as 1910, was considered fairly satisfactory even without chlorination. This fact illustrates the increasing demand on the part of the public for water supplies of the highest degree of purity.

J. W. Ellms, G. W. Hamlin, A. G. Levy, and J. E. A. Linders, Members, Am. Soc. C. E. (by letter).—The engineers who have so kindly discussed this paper have brought out a number of points in the design which are worthy of further comment.

The question asked by Mr. Van Loan relative to the operating results with the hydraulic-jump mixing flumes, may be answered by calling attention to the results obtained from five years of successful operation. These flumes have efficiently mixed the alum solution with the raw water, and the flocculation following the jumps has been entirely satisfactory.

The use of an alum solution instead of dry feed does depart from the general trend of present-day practice, as mentioned by Mr. Chase. The writers are fully aware that this is the case, but experience has shown that accurate and uniform, and consequently economical, application of the coagulant has been obtained at the Baldwin Plant.

The preparation of a dilute alum solution of uniform strength by the method used at the Baldwin Plant, namely, the dissolving of a weighed quantity of alum by the upward flow of a measured volume of water, is an extremely simple process; and when the solution is properly agitated before using, does not require laboratory supervision. The writers are firmly convinced that the continuous uniform measurement of a liquid is more accurately and more easily obtained than the continuous measurement of solid particles.

The experimental work[19] upon which the design of the hydraulic-jump flumes was based, conclusively demonstrated the thorough mixing action produced by this method. In this work the exploration of the jump with Pitot tubes showed water currents moving in all directions within the jump. The writers cannot conceive of any form of mechanical stirring which would produce "a more commensurate initial jarring of the water", as stated by Mr. Jenks, than that obtained in the hydraulic jump.

The Baldwin Plant was designed, in the section providing for the preliminary treatment, on the basis of two steps: First, for a practically instantaneous, thorough, and intimate mixing of the chemical coagulating

[18] "The New Purification Plant of the Greenwich Water Company," *Journal*, New England Water Works Assoc., Vol. LXII, No. 4 (1928).

[19] "The Hydraulic Jump as a Mixing Device," by A. G. Levy and J. W. Ellms, Members, Am. Soc. C. E., *Journal*, Am. Water Works Assoc., January, 1927.

solution with the water; and, second, for a gentle agitation of the entire flow of the treated water over a period of time to permit of the agglomeration of the floc. The purpose of the first step was simply one of mechanically mixing the alum solution with the water, and the element of time is immaterial provided thorough mixing is effected. The elements of time and velocity, however, do enter into and play a very important part in the second step of the process, namely, the agglomeration of the colloidal particles into a floc formation. The second step in the process is accomplished at the Baldwin Plant in the large conduit, equipped with sets of "over and under" baffles, which connects the hydraulic-jump mixing section with the coagulation basins. The length of time required for this secondary agitation depends upon the character of the water being treated, and the quantity of coagulant added. In experimenting with Lake Erie water, the writers found that this time period need not be longer than 5 or 6 min., with a velocity of 0.75 to 1.00 ft. per sec. A pin-point floc is characteristic of Lake Erie water treated with alum as the coagulant. The usual small quantity of suspended matter in Lake Erie water may account for the small size of the floc formed.

The writers agree with Mr. Jenks that the loss of head through the hydraulic jump is comparable with that in the conventional type of baffled mixing chamber; but they seriously question whether the same degree of thorough and rapid mixing of the chemical with the water is obtained in the baffled chamber.

The design of the Baldwin coagulation basins was based on a theoretical velocity of flow and a definite period of detention. It was considered desirable to have an average velocity of 2 to 2.5 ft. per min., and a detention period of 4.5 to 5 hours.

Continuous sludge removal was not permissible at the Baldwin Plant because the sludge could only be removed in the spring and fall months.

More shallow sedimentation basin design than is commonly used appears to have a reasonable basis from theoretical considerations. However, certain practical deductions from observations extending over many years, with many different types of water, lead the writers to believe that efficient sedimentation of suspended matter, with a specific gravity as close to that of water as is produced by coagulating Lake Erie water with alum, requires average depths of not much less than 15 ft. It will have to be proved that in so mobile a liquid as water the velocities in basins of only about one-half this depth are not destructive of efficient sedimentation in the lower strata of water at and near the bottom. The writers believe caution should be used in applying the over-flow rate theory as at present developed. One questionable point is the relationship between total depth and the overflow rate depth. Whatever factor may be used for this ratio would seem to be affected materially by the character of the suspended particles. As variations in temperature of the water will change its viscosity, it does not seem improbable that efficiencies of coagulation basins may be affected by this fact, as noted by Mr. George G. Nasmith.[20]

[20] "The Trial Filtration Plant, Ottawa, Canada," by George G. Nasmith, *Journal*, Am. Water Works Assoc., August, 1930.

The hydraulics involved in the design of a filter plant is of the utmost importance and affects its successful operation. Experience has proved that the greatest care and skill are required in making the computations involved in the various hydraulic problems entering into the proper design of a filtration plant. When these computations are carefully made, it will be found that the actual hydraulic gradient through the filtration plant will be in very close agreement with the theoretical gradient as calculated.

Good design involves the proper velocities in mixing the coagulant with the water, in secondary agitation to produce proper flocculation, in channels and through sluice-gates to prevent breaking up the floc, and in coagulation basins to permit of effective sedimentation. Adequate available head for filter operation and for washing filters should also be provided. Gutter and drain capacities for wash water, when used at the highest rates of flow, are imperative to permit proper cleaning of the filters. Unless all these points of design are carefully considered and properly calculated an efficient plant cannot be constructed.

An additional feature of the purification process at the Baldwin Plant not originally contemplated has been the adoption of the ammonia-chlorine process of disinfection, by which the problem of chloro-phenolic tastes appears to have been solved. No such objectionable tastes have been noted since the adoption of this process at the Cleveland filtration plants in January, 1930.

The writers are glad to note that Mr. Herron finds the cost data to be of value and in convenient form for use. The writers believe them to be one of the most important features of the paper.

# LAMINATED ARCH DAMS WITH FORKED ABUTMENTS[1]

By Fred A. Noetzli,[1a] M. Am. Soc. C. E.

With Discussion by Messrs. Lars R. Jorgensen, William Cain, B. F. Jakobsen, P. Wilhelm Werner, H. B. Muckleston, Fredrik Vogt, Paul Bauman, F. W. Hanna, A. A. Eremin, and Fred A. Noetzli.

Synopsis

This paper describes some modifications of arch dam form and layout, as compared with usual current practice, which are believed to promote both simplicity of design and economy. Simplicity of design is achieved by the use of structural proportions that avoid the complexities of the "thick arch", and economy, fortunately, follows in consequence.

That the controlling principles hereafter noted, and the ends to be sought, are now recognized in some quarters, is evidenced by several recent dam designs, but it is believed that this conception may advantageously be carried further than it was in these instances. The purpose of this paper is to present the orderly development and application of certain basic principles, carried to their logical conclusion.

It is apparent that the efficient concrete arch is one in which the stresses are approximately equal across any section; that is, in which the line of thrust approximately coincides with the neutral axis. This condition is most nearly obtainable in a dam composed of thin arches; it is impossible to secure in "thick arches." Furthermore, as arches depart from the "thin" classification, and approach the "thick", the relation between the radius, the thickness, and the central angle, has important consequences upon the stress distribution; and, other things being equal, the maximum angle will generally give

[1] Published in February, 1930, *Proceedings*.

[1a] Cons. Hydr. Engr., Los Angeles, Calif.

minimum stress. With these considerations in view, a typical structural form and layout has been developed by the writer, such as will permit their attainment to the maximum practical degree. The topography at the dam site is obviously a controlling feature but, for typical conditions, the desired results are obtained by:

1.—The use of a special type of buttress to take the thrust of the upper arch elements, thereby reducing the required maximum arch span, and hence the maximum radius.

2.—The pronounced sloping, up stream from the crest, of the crown of the dam, thereby securing the minimum radii for the lower arch elements.

3.—By the subdivision, where indicated, of the total arch thickness into two or more separate arches, or arch laminæ, thereby keeping the arches "thin", or relatively so, and maintaining throughout the dam the corresponding advantages.

Principle 1 requires the use of gravity wings which are so related to the buttresses as greatly to increase the strength of the latter, and to provide ample assurance against over-stress in this quarter. Principles 1 and 2 have been applied by the writer to the design and construction of a dam hereafter described. The method of lamination has been adopted in principle by French engineers on a large dam. It is believed that the method proposed by the writer is equally as effective and possesses some advantages over the French design.

## Introduction

The first arch dams were designed by the simple cylinder formula. Most of these structures are of moderate span and height, and the unit stresses assumed in the design were relatively low. No arch dam designed by this method has failed for reasons of structural weakness. This speaks rather well for the adaptability of such structures to the loads and stresses caused by the water pressures.

A great improvement in the design of arch dams accompanied the application of the elastic theory. Few other branches of structural engineering have received, during the years since 1920, as much attention as dams of the arch and multiple-arch type. This is evidenced by the large number of theoretical studies published during this period in the United States and in foreign countries.[2] Tests and experiments were made on a number of dams and on laboratory models, to determine within reasonably close limits the laws of the distribution of stresses in arch dams. The most signal advance in this connection was the construction and successful testing of the Stevenson Creek Experimental Arch Dam by the Committee of Engineering Foundation on Arch Dam Investigation. Much valuable and useful information has been obtained from these theoretical and experimental studies.

[2] See Bibliography in Report on Arch Dam Investigation, *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, p. 277.

Theoretical investigations have shown that, for thick arches of dams, certain assumptions ordinarily made in the analysis of relatively thin arches—as used in arch bridges and arch dams of moderate height and span—could be improved upon, and the theory of thick arches was developed. However, apparently it was found that this theory has a rather limited field of application, since it often becomes necessary to abandon the actual arch as a structural element, and have recourse to a contained "secondary arch".[3]

This "secondary arch" is assumed to support the entire water load, and is analyzed accordingly. The basic assumption related to these secondary arches, inside the primary thick arch, is that numerous cracks are formed in the tension zone of the latter; that is, on the extrados at the abutments and on the intrados at the crown. In other words, the most advanced theory serves to show that, in some instances, the structure cannot function as built, and in such cases it is customary to neglect the concrete that is presumably cracked or in tension. The conditions which determine the secondary arches are very complex, and involve some rather uncertain assumptions; but even if this solution were clean cut and definite, it would still be open to the objection that to place deliberately in a dam concrete which it is assumed will be structurally inoperative, is not in accord with efficient design or engineering.

In his early studies of arch dams the writer was impressed with the difficulties involved in a theoretically exact analysis. His further studies, and the knowledge derived from the published work of others, have served to strengthen his original impression. It appears that each advance made in the development of the structural theory has not only introduced additional mathematical complications, but necessarily has involved fundamental assumptions which are admittedly uncertain of determination. In other words, despite the great advance that has been made in mathematical analysis of arched dams in recent years, the inherent complexities and uncertainties of the problem are still present.

When a structural type is such that its analysis is complicated and uncertain beyond a reasonable degree, and when it is evident that primary structural elements cannot function as built, a modification of type, such as to result in simple relationships, is perhaps indicated. Great complexity of design can only be justified by producing corresponding efficiency, which is questionable in the case of the present thick arch dams.

Some of the major difficulties encountered in the analysis of the current type of arched dam are results of the use of thick and flat arches. The consequent complications introduced are twofold: First, as regards the action of the arches themselves, and, second, the action of the stiff cantilever elements, and their influence upon the arches. It is known that the action of a thin arch under water loads, as in the upper part of a thin arched dam, is relatively simple and determinate. It may also be readily shown that, regarding arching action only, the thin arch is usually far more efficient than the thick. So far as the arches themselves are concerned then, it would obviously be desirable to keep them as thin as possible, within practical limits. As the thickness of the arches is reduced, the flexibility of the vertical or cantilever

[3] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 475.

elements is increased in very much greater proportion, resulting in a greatly reduced influence of these elements, and an increase in the proportion of load carried by the arches.

On the other hand, an increase in the efficiency of the cantilever elements (by increasing their thickness) can only be accomplished at the expense of reduction of arch efficiency. In other words, it is assumed that the thin and efficient arch may be taken as the goal of attainment, without any material sacrifice of other benefits.

With the preceding considerations in view, the writer for some time past has devoted his efforts toward the development of a type of arch dam which would eliminate or reduce some of the difficulties and complexities of the current thick arch type, and, at the same time, give a structure of greater efficiency. The purpose of this paper is to describe the type of structure evolved and the manner in which the desired ends are accomplished.

In what has preceded, it was stated that the thin arch, subjected to water loads as in a dam, possessed marked advantages over the thick arch under similar conditions. This fact is probably well understood, but it will be pertinent to summarize here these relations in greater detail.

As has been shown by recent investigations, the influence of rib-shortening, temperature, and shrinkage becomes very marked as the arch thickness is increased. Their effect is to create an eccentricity of the resultant thrust, and, therefore, an unequal distribution of pressure across the section, tending toward or developing tension at the crown intrados and at the extrados at the abutments. The fact that these important influences are neglected in the cylinder formula is one of the main reasons that this is not applicable to thick arches.

In all, or most all, the theoretical investigations of the arched dam, the analysis has been based upon horizontal elementary arches, consequently subjected to uniform normal water pressure. That is, these are assumed to be the primary elements, or those carrying the maximum stress. Depending upon the layout of the dam, and other considerations, the actual primary elements may be horizontal or inclined, but it is probable that conclusions pertaining to horizontal elements will be applicable in kind to inclined elements, and will serve as a measure of the conditions obtaining in the latter. The complexities introduced by a consideration of inclined elements would prohibit any generalized theory or conclusions, in the interests of which it is permissible to adopt the horizontal arch element as the argument, realizing that the results thus obtained may be subject to subsequent modification. In this, the writer follows his predecessors.

## Notation

The following notation is used in the paper:

$t$ = thickness of arch, in feet.
$r$ = mean radius of arch, in feet.
$R_u$ = radius of extrados, in feet.
$R_d$ = radius of intrados, in feet.
$y$ = ordinate of any point on the arch axis.

$\phi$ = angle described by any radial line moving from the crown toward the abutment.
$\phi_1$ = one-half the central angle, in degrees.
$\sigma_c$ = cylinder stress, in pounds per square inch.
$\sigma_r$ = rib-shortening stress, in pounds per square inch.
$\sigma_T$ = stress corresponding to a drop in temperature.
$H_T$ = normal pull due to a drop of temperature per foot width of arch, at the crown.
$H_r$ = normal rib-shortening at the crown per foot width of arch.
$p'$ = normal radial pressure, in pounds per square foot, on extrados.
$T$ = temperature drop, in degrees Fahrenheit.
$n$ = number of laminæ in the arch dam under consideration.
$e$ = coefficient of thermal expansion.
$E$ = modulus of elasticity of arch, in pounds per square inch.
$C$ = coefficient determined from Figs. 1 and 2 (see Equation (5)).
$K$ = coefficient determined from Figs. 3 and 4 (see Equation (7)).

## Analysis of Stresses in Circular Arches by Means of Charts

From formulas and diagrams[4] by William Cain, M. Am. Soc. C. E., it is shown that, other things being equal, the rib-shortening and temperature stresses are determined by the central angle, $2\ \phi_1$, and the ratio, $\frac{t}{r}$, of the arch thickness to the mean radius. It is evidently desirable to use such values of these quantities, in so far as may be practicable, as will give minimum values of these stresses, and, hence, maximum efficiency of the arch.

The normal rib-shortening pull at the crown, per foot width of arch, is given by the equation,[5]

$$H_r = -\frac{K'}{12}\, p'\, R_u \left(\frac{t}{r}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

wherein, $K' = \dfrac{2 \sin \phi_1}{D_s}$.

Likewise, the equation for cylinder stress is,

$$\sigma_c = \frac{p'\, R_u}{144\, t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Transposing algebraically to determine a value of $p'\ R_u$ and substituting this value in Equation (1),

$$H_r = -\ 12\ K'\ \sigma_c\ t \left(\frac{t}{r}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The rib-shortening stress at any section may be expressed by,

$$\sigma_r = -\frac{H_r \cos \phi}{144\ t} \pm \frac{H_r\, y\, r}{24\ t^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Substituting the value of $H_r$ from Equation (3), combining and reducing, Equation (4) becomes,

$$\sigma_r = \sigma_c \frac{K'}{12} \left(\frac{t}{r}\right)^2 \left[-\cos \phi \pm 6\, y \frac{r}{t}\right] = C\, \sigma_c \quad \ldots\ldots\ldots\ldots (5)$$

[4] "The Circular Arch Under Normal Loads," *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 233; see, also, "Design and Construction of Dams," by Edward Wegmann, M. Am. Soc. C. E., Eighth Edition, 1927, chapter on "Multiple-Arch Dams."

[5] "Design and Construction of Dams," by Edward Wegmann, M. Am. Soc. C. E., Eighth Edition, 1927, Equation (9), p. 445.

thus giving the rib-shortening stress in terms of the cylinder stress. For a drop in temperature, the normal pull at the crown per foot width of arch is given by the equation,[6]

$$H_T = -\frac{K'}{12} E e T t \left(\frac{t}{r}\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

In this equation, $T$ is considered positive, $E$ is in pounds per square foot, and $t$ is in feet. After reducing $E$ to pounds per square inch this expression is identical with Equation (3), except that $\sigma_c$ is replaced by $E e T$. The equation for temperature stress at any section may be developed to read,

$$\sigma_T = E e T \frac{K'}{12}\left(\frac{t}{r}\right)^2 \left[-\cos\phi \pm 6 y \frac{r}{t}\right] = C E e T \ldots\ldots (7)$$

in which, $C$ is the same as in Equation (5). In other words, after certain simple quantities have been computed, the same coefficient, $C$, is applicable to determine both the rib-shortening and temperature stresses.

Values of $C$ corresponding to extrados and intrados at both crown and abutment have been computed and plotted on Figs. 1 and 2. It is believed that these curves present the required values in such form as to give a clear picture of the influence of the variables, over a wide range.

It will be observed that when $\frac{t}{r} = 0$, the value of $C$ is zero for all values of $2\phi_1$. In other words, as $\frac{t}{r}$ approaches zero, the stress approaches the simple cylinder stress. It is interesting to note also that (within the range of the curves), except for very large angles, the coefficient, $C$, and, hence, the stress, increases as $\frac{t}{r}$ increases from zero up to some point, and then decreases with further increase in $\frac{t}{r}$. In some cases, and for the smaller angles, the maximum value of the stress corresponds to relatively small values of $\frac{t}{r}$. Also, for some values of $\frac{t}{r}$, the stress may be smaller for smaller angles. Both these facts are perhaps contrary to what would be expected. In other words, the curves show that not for all conditions the rib-shortening and temperature stresses are decreased by decreasing the arch thickness and increasing the central angle.

The sign of the coefficient, $C$, determines the sign of the rib-shortening stress, $\sigma_r$, and also that of the temperature stress, $\sigma_T$, for a drop in temperature, which generally is the only direction that need be considered. The total stress due to load is evidently equal to,

$$\sigma_c + \sigma_r = \sigma = (1 + C)\,\sigma_c \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Obviously, there is tension on the section when $C$ is negatively greater than $-1.0$, so that the horizontal representing this value on the charts defines the limiting conditions for absence of tension due to load forces.

[6] "Design and Construction of Dams," by Edward Wegmann, M. Am. Soc. C. E., Eighth Edition, 1927, Equation (14), p. 448.

From the standpoint of design, it may sometimes be advisable to fix $\sigma$ and to secure such values of $\frac{t}{r}$ and $2\,\phi_1$ as will accord with this. To satisfy this condition, the value of $\sigma_c$ must equal $\frac{\sigma}{(1+C)}$, which must be obtained by trial.

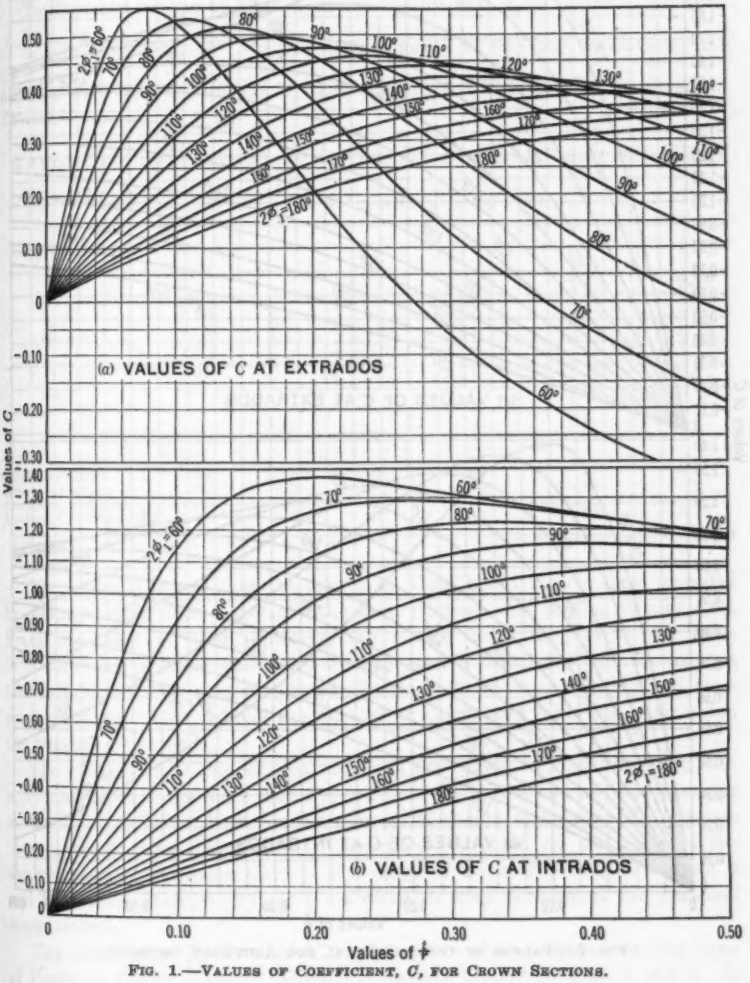

FIG. 1.—VALUES OF COEFFICIENT, $C$, FOR CROWN SECTIONS.

An inspection of the curves will show that the maximum compressive stress will occur at the abutment intrados (Fig. 2(*b*)), and the minimum compres-

sion or maximum tension at the abutment extrados. Fig. 2(*a*) shows that for even moderately large angles and fairly small values of $\frac{t}{r}$, the tensile

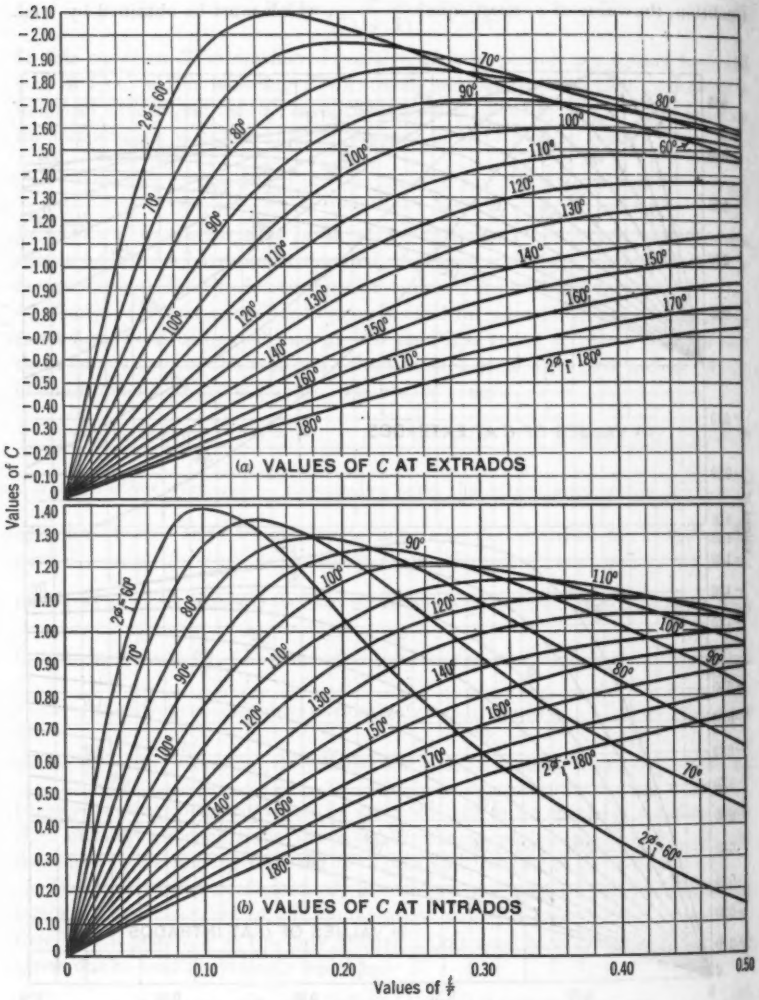

FIG. 2.—VALUES OF COEFFICIENT, *C*, FOR ABUTMENT SECTIONS.

stresses, due to load only, may become very large. These would be further increased, of course, by the temperature stresses, so that the combined stress may readily become critical.

The direct stress is equal to $\sigma_c$. The rib-shortening stress is equal to $C\,\sigma_c$ and the temperature stress is approximately equal to $15\,T\,C$. The coefficient, 15, corresponds to $E = 3\,000\,000$ lb. per sq. in., and $e = 0.000005$, which are probably reasonable average values. In the Stevenson Creek Test Dam an average value of $E = 3\,600\,000$ lb. per sq. in. was found.[7] The change of temperature, $T$, is expressed in degrees Fahrenheit (negative for a drop).

To illustrate the use of Figs. 1 and 2, assume that $\sigma_c = 350$, $2\,\phi_1 = 110°$, $\frac{t}{r} = 0.10$, and $T = 10°$ (drop). It is required to find the stresses at the extrados and intrados, at crown and abutment. The solution is given in Table 1.

TABLE 1.—COMPUTATIONS TO DETERMINE STRESSES WHEN $\sigma_c = 350$, $2\,\phi_1 = 110°$, $\frac{t}{r} = 0.10$, AND $T = 10°$ DROP.

| Section. (1) | Cylinder stress, in pounds per square inch. (2) | Coefficient, $C$. (3) | Rib-shortening stress, in pounds per square inch = Column (2) × Column (3). (4) | Total load stress, in pounds per square inch = Column (2) + Column (4). (5) | Temperature stress, in pounds per square inch, = 15 × 10 × Column (3). (6) | Total stress, including temperature, in pounds per square inch. (7) |
|---|---|---|---|---|---|---|
| Crown, extrados..... | 350 | 0.31 | 108 | 458 | 46 | 504 |
| Crown, intrados..... | 350 | −0.39 | −136 | 214 | − 58 | 156 |
| Abutment, extrados.. | 350 | −0.70 | −245 | 105 | −105 | 0 |
| Abutment, intrados... | 350 | 0.65 | 227 | 577 | 97 | 674 |

The writer is aware that the curves in Figs. 1 and 2 have been preceded by others, devised with essentially the same purpose, and serving it very well. From his point of view, however, the curves herewith present the facts in a somewhat simpler and more directly usable form, particularly in that the coefficient which they give is applicable both to rib-shortening and temperature stress. This reduces the number of charts and functions with which the designer must deal.

The coefficients, $C$, can be obtained from the curves without difficulty, with a probable error of not more than 1% or 2% of the higher values. The accuracy is, therefore, sufficient both for the purpose of design and analysis of stresses in arches, of given dimensions. They were computed on the basis of the theory given by Professor Cain.[8] The range of the coefficients, $C$, in Figs. 1 and 2, is from about $-2.1$ to $+1.4$ which is very convenient for practical computations.

The coefficients, $K$, for "thick" arches, were also computed on the basis of Professor Cain's theory.[9] These values were plotted in Figs. 3 and 4. It

[7] *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, p. 155.
[8] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 233.
[9] *Loc. cit.*, Vol. 90 (1927), p. 522.

should be noted, however, that the values of $K$ correspond to $(1 + C)$ in Figs. 1 and 2. The total load stresses, therefore, are obtained directly by the relation: Total load stress is equal to $K$ times the cylinder stress.

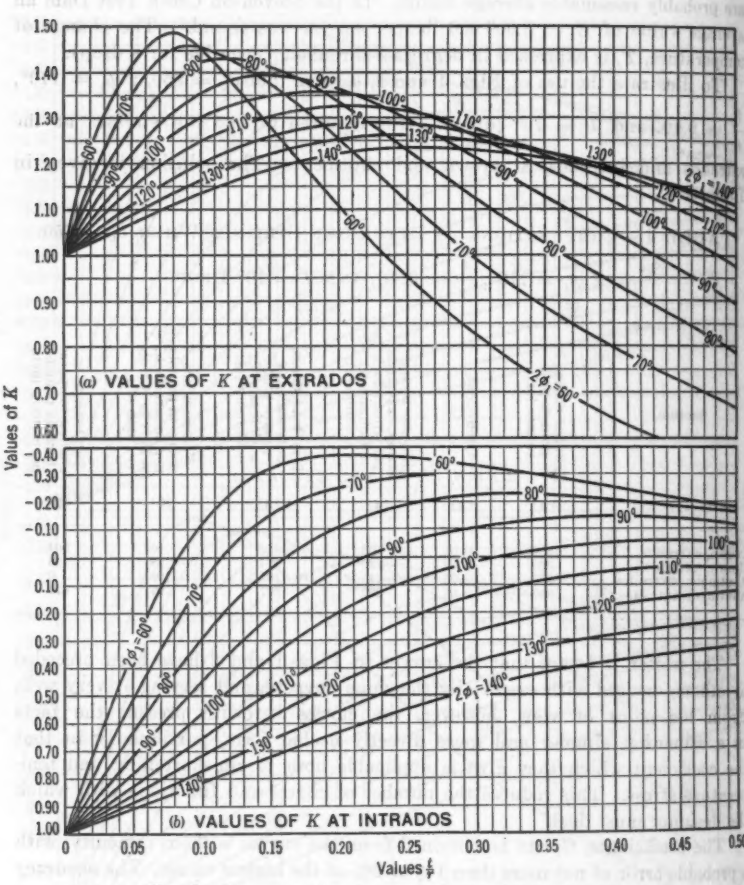

FIG. 3.—VALUES OF COEFFICIENT, $K$, FOR CROWN SECTIONS.

A comparison of the two sets of diagrams shows that for relatively thin arches there is only a small difference between the values of $K$ and the corresponding values of $(1 + C)$. The difference becomes more marked for thicker arches, that is, for the larger values of $\frac{t}{r}$. For designing purposes it is advisable to use Figs. 3 and 4 to find values of $K$ for thick arches. For computing the stresses due to temperature changes, Figs. 1 and 2 may be used with close approximation.

## Laminated Cone Arch Dam with Forked Abutments

The proposed structure to which reference is taken, is shown in Fig. 5 in a typical layout. It is called Dam No. 1 and is a laminated cone arch dam with forked abutments. This structure has been developed in the pursuit of

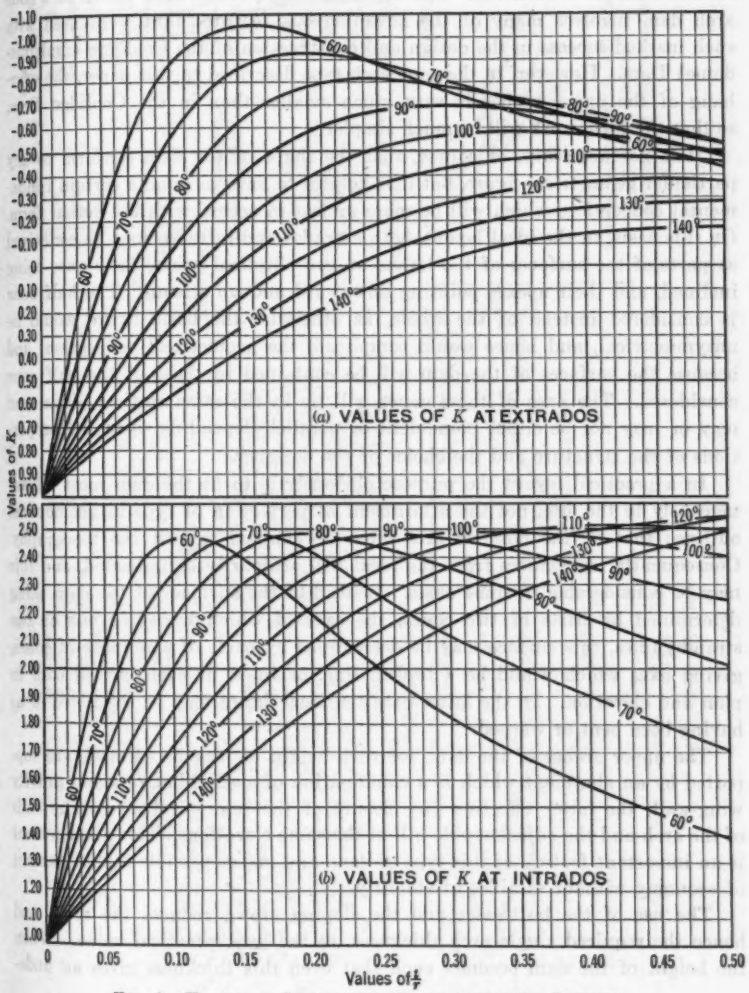

Fig. 4.—Values of Coefficient, $K$, for Abutment Sections.

the ideal, as outlined previously. It is believed that the purposes are accomplished with reasonable success. The diagram shown is a preliminary layout, and doubtless would be subject to some modification for a final design. It is given to illustrate general properties only.

For simplicity of layouts, and because this is sufficient for preliminary design, the arch sections are made circular in horizontal planes, with radii decreasing from crest to foundation. The crown of the dam is given a pronounced slope up stream below the crest, making this section overhang down stream from its foundation. The up-stream slope of the arch crown of a cone arch dam involves many of the advantageous features that were used with such marked success in the design and construction of the Coolidge (multiple-dome) Dam. However, in the cone arch type described in this paper, the overhang of the upper arches is very much smaller than in the Coolidge Dam, so that the form work will be much simpler.

It is not necessary, of course, that the shape of the dam conform to any particular geometrical figure, but it is helpful to have in mind a certain fundamental conception, which will be more or less in accord with the actual form. On this basis, in the ideal layout, both extrados and intrados may be conceived as parts of the surfaces of the halves of two elliptical cones, their axes being inclined, and their apexes pointing downward and up stream. The half cone is considered instead of the whole, as otherwise the basic figure would be unsymmetrical, and hence would complicate the geometrical conception, and because the surfaces of the dam will be contained in those of the half cone considered. The axes of these cones will lie in the same vertical plane, and may or may not be either coincident or parallel, depending upon the proportions of the structure and the choice of the designer.

In a practical layout the purpose obviously is to fit the dam most advantageously to the site, not the attainment of perfection of type in geometrical outline; that is, the circular arcs must be adapted to suit the topography. Consequently, departures from the ideal will ordinarily be indicated, and this may be considerable in some cases. Instead of the surfaces of the dam being determined by parts of two cones, the axes of which would be one or two straight lines, this surface may be determined by parts of a number of cones, giving axes which would be a broken line, or lines, or even curved both in plan and elevation. In the latter case the ideal figure may be conceived of as having been bent or warped.

The upper arches of the dam, for such height as may be suitable, are supported by an abutment which is a combination of special buttress and gravity wing-wall, the latter effecting the closure of the reservoir between the ends of the arch and the adjacent side hill at the same elevations. This arrangement is an important feature of this type of dam, and makes possible the attainment of economy without sacrifice of stability.

The use of the buttresses and the sloping crown reduces the radii, and hence the required single arch thickness, to the least practical value. When the height of the dam becomes such that even this thickness gives an undesirably high value of $\frac{t}{r}$, the thickness is further reduced by substituting two or more concentric arch rings in contact, for the single arch that would otherwise be required for the direct stresses. In other words, the arch is lami-

FIG. 5.—DAM NO. 1, CONE ARCH TYPE.

nated as required to keep the values of $\frac{t}{r}$ acceptably low, except that the number of laminations, of course, must be kept within practical limits.

The idea of the cone-shaped arch dam is not new, although it is believed that the present application of the idea is different in several respects from its predecessors. There is nothing to prevent the variable radius arch dam from assuming the form of a cone, and the later developments of this type appear to be in that direction. However, it is believed that none of these developments of form, to date, has secured the maximum obtainable benefits, nor have such developments pointed out the principles through application of which these advantages are to be gained.

The idea of arch laminations, in the manner suggested, is one which occurred to the writer some years ago, but in the sense of actual application in principle, it already has a precedent in a large dam in France, which will be fully described hereafter.

## General Principles of Cone Dam Layout

The actual topography of the site is, of course, the governing feature in any dam layout, which should be such as properly to fit the ground and, at the same time, satisfy the desired theoretical properties. In any actual layout, some compromises must be made between these two aspects of the problem. There are certain general principles, however, which can usually be adopted to control the layout, and which will do so in the case of the typical site to which arch dams are adapted.

Symmetry of the arches about the crown is obviously desirable, and to secure this the axis of the cone should lie in the same vertical plane as the principal axis of the canyon at the dam site; that is, essentially parallel to the foundation contours in the vicinity of the mid-height of the dam. Unless an artificial abutment is provided, the arch element at any elevation ends at its intersections with the foundation contour of the same elevation. Furthermore, in any vertical plane, there should be an easy and suitable transition between the surfaces of elements at different elevations; that is, the position of the axis and the slope of the crown being fixed, the radius at any elevation will be determined by the condition that the arc must pass through the crown point, and must intersect the foundation contours of the same elevation, at a point which satisfies the required outline of the structure. It follows, therefore, that there will be a certain relationship, although indeterminate, between the radii and central angles throughout the dam, the form of each element being determined in a measure by that of the one previously determined. The primary arch element to be established in a dam layout is naturally that one at the crest, and for the reasons previously stated, it is important that this be so chosen as to satisfy the desired conditions in the dam as a whole.

Within practical limits, it is the purpose of this layout to obtain minimum radii of arch elements and reasonably large central angles at the different elevations, but this does not mean absolute minimum radii. It is always

possible to decrease the radii by increasing the central angle, but beyond a certain point this would be wasteful. Furthermore, if the radii in the bottom of the dam become too small, the shape of the corresponding arches is not acceptable. Accordingly, the crest arch element should have a fairly large radius, consistent with a central angle of about 80 to 100° between the controlling abutment points.

## Functions of Forked Abutments

The primary function of the forked abutments is to decrease the span, and hence the radius that otherwise would be required for the crest and other upper portions of the arch. This should be done without introducing any uncertainties of structural action, or failing to provide in full for the requirements of an arch abutment. Incidentally, the abutments promote symmetry of the arches, which is very desirable, as indicated by the tests on the Stevenson Creek Experimental Arch Dam.

Generally, the two forks of the abutment are placed in such directions relative to the direction of the arch thrust that the thrust is divided into two components supported by the buttress proper and the gravity wing-wall, respectively. The topography at the dam site is usually the guiding factor for the best feasible arrangement of the two forks of the abutment.

For the purposes of design, the buttress is assumed to support its component of the reaction of the abutting horizontal arches. The thickness of the buttress at any elevation is constant and the same as the end of the arch at that elevation. Consequently, the buttress may be considered to be formed by extensions of the horizontal arches.

To insure safety of the buttress against sliding, in addition to the ordinary construction precautions, the layout of the dam should be such that the base of the buttress slopes up the hillside from the end of the arches. From the same point, the top of the buttress may slope downward at the rate of 2:1, 3:1, or any other suitable slope warranted by the conditions.

The height of the buttress, of course, is determined by judgment and economy, but in the writer's opinion there is one consideration which may be given some weight, providing an additional safety factor.

Since the crown of the dam is sloping, the actual load-carrying arch elements will be inclined, and hence only a part of the arch load above the bottom of the buttresses will be transmitted to them. The exact inclination of the true elementary arches cannot be given as a generality, but it will probably be approximately correct to assume them as normal to the slope of the arch crown. If the latter is taken at 4:10, the slope of the normal arches will be 10:4 with the horizontal. The height of the buttress can then be made such that the top inclined arch element (through the crown), if produced, would intersect the base of the buttress and thereby abut directly against the rock foundation. Actually, then, the upper portion of the buttress will receive the reaction only from that part of the dam lying above the uppermost inclined elementary arch. The stability of the buttress, therefore, would appear to be established beyond question, if its down-stream slope is as flat or flatter than, say, 2:1. In fact, the horizontal arch elements abutting against

the buttresses will act more or less monolithically with the buttress. The buttress could evidently not be overturned or otherwise overstressed without the entire arch-buttress monolith functioning. Horizontal keyways in the planes of the vertical joints in the arch and between arch and buttresses will tend further to make monolithic action positive. Steel reinforcement extending from the lower parts of the arch upward toward and into the buttresses would give an additional assurance of monolithic action, but such reinforcement, in general, is not necessary.

That the arches of arch dams function more or less monolithically is clearly proved by the fact that recently in two arch dams one abutment was washed away leaving the upper arches without direct support. Nevertheless, the arches, as such, did not fail.[10]

The gravity wing-wall, which, together with the buttress proper, forms the forked abutment of the arch, will also effect the closure of the reservoir between arch and side hill. This wall is supporting its share of the direct water pressure by ordinary gravity action and also the component of the arch thrust acting in its direction. The cross-section of the gravity wing adjacent to the arch is usually relatively large and the stresses from gravity action are very small.

The component of the arch thrust acting on the gravity wing-wall, stresses it in an axial direction; that is, perpendicularly to the stresses from gravity action. The gravity wall abuts laterally against the rock foundations, and the arch thrust component in the gravity wall is thereby transmitted directly to the rock. Assuming a properly stepped foundation, a sliding up hill, or an overturning of the gravity wing in a longitudinal direction, due to the arch thrust component, is naturally a rather remote possibility.

Under normal conditions, a relatively small proportion of the arch thrust may be supported by the gravity wall branch of the forked abutment. It is evident, however, that because of its greater cross-section and consequent smaller deformation, the gravity wing-wall would take an increasingly large proportion of the arch thrust if the primary buttress should be subjected to unforeseen overloads such as might cause it, if acting alone, to approach the point of yielding, due either to excessive concrete or foundation stresses.

The gravity wing-wall serves, therefore, with the same amount of material two distinctly different purposes, wherein lies one of the main advantages of the forked type of buttress.

It is true that a so-called gravity tangent may work on the same principle. However, in general, a gravity tangent will not permit of decreasing the span of the arch as much as a forked abutment, except by running it almost parallel to the contour, which is objectionable. Furthermore, a gravity tangent built along a transverse slope is likely to have its base also on a considerable cross-sectional slope. The sliding factor of the gravity abutment would thus be very high. In addition, the arch has a tendency to deflect down stream and, therefore, it exerts an appreciable torsional reaction on the supporting sections of the gravity wing. This action, combined with the shear

[10] *Engineering News-Record*, Vol. 97, October 14, 1926, p. 616.

due to rib-shortening and temperature, results in an additional force upon the gravity wing for which this is not ordinarily designed. In other words, a gravity tangent to an arch dam is probably the weak link, whereas the forked buttresses as here indicated are believed to be the strongest part of the structure.

### Effect of Sloping Crown

The arches of the cone type dam are circular in a horizontal plane, but because of the sloping crown of the dam, and in accordance with the law of least work, the actual working elementary arches will be inclined. The effect of this on the probable reaction carried by the buttresses has been noted. It is evident, also, that the inclined elementary arches possess the advantage of carrying their reaction downward into the foundation, instead of horizontally.

The slope of the cone type of dam permits a much greater variation of the arch radii between crest and base than in the ordinary type of variable-radius arch dam. Thus, for a given span and corresponding radius at the crest, the radii of the lower arch elements can be decreased considerably, usually to one-half or less of the length of the radius at the crest. At the same time the central angles of the elementary arches of a cone dam can be kept reasonably large, say, 100 to 110°, or more, resulting in a better distribution of the stresses over the arch section, for reasons previously given.

Another feature of the sloping crown, and consequent overhang of the central part of the dam down stream from the footing, is that this makes the structure particularly suitable as an overflow dam. By confining the overflow to the central part of the crest, the falling sheet of water will be thrown well down stream from the footings, thus reducing the possibility of critical erosion. Depending upon the character of the foundation material and other conditions, it may be permissible to allow the formation of a natural pool; otherwise, a suitable artificial pool may be created by the construction of a down-stream weir.

### Effect of Laminations

The planes of lamination are concentric, are essentially smooth and true, and the surfaces are painted with asphalt, or other suitable joint material, permitting minute movements and adjustments between the separate arch sections. The typical manner in which the structure is laminated is shown in Fig. 5.

The structural functioning of a laminated arch dam is approximately as follows: The full water pressure in the reservoir acts on the up-stream face of the up-stream arch lamina. Under such pressure this first arch lamina will be deflected. The immediate contact with the second lamina will put this one under stress, inasmuch as the up-stream arch can not deflect without deflecting and stressing the second arch. This latter will take a proportionate amount of the water load according to its thickness and other dimensions governing its stiffness and strength. In case of additional arch laminæ, a further division of the water load between the first, second, and the additional

laminæ will take place. Thus, neglecting for the present the effect of cantilever action, each arch lamina will take such a proportion of the total water load that the deflections of corresponding points along radial lines will be the same for all arch laminæ.

Assume, for instance, a horizontal slice, 1 ft. high, which may be composed of, say, three arch laminæ of equal thickness and span, as shown in Fig. 6. The radial water pressure will be divided between the three arches inversely in proportion to their deflections under a unit of load. The actual deflections, of course, are the same for all three arches, if the compression of the concrete in a radial direction is neglected.

If the radii, thickness, and central angles of the individual arch laminæ were exactly the same, it is evident that the water pressure would be divided equally between the three arches in order to produce the same deflections.

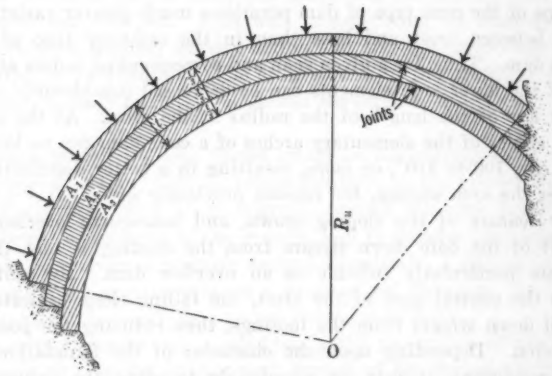

FIG. 6.—HORIZONTAL SECTION THROUGH A LAMINATED ARCH DAM.

However, the arch radii will differ by lengths corresponding to the thickness of the arch laminæ, and the radii of the down-stream arches will always be smaller than those of the up-stream arches. On the other hand, the down-stream arches will usually have a larger central angle than the up-stream arches. Generally, these two factors will tend to compensate each other as regards their influence on the deflection of the various arch laminæ and their ability to carry their proportion of the load.

It will be a relatively simple matter to determine in each case the proportion between the thicknesses of the individual arch laminæ, in order to secure approximately the same stresses in all of them.

The joints between the arch laminæ incidentally will subdivide the vertical cantilevers of the dam into cantilever laminæ. The deflection of a cantilever under a given load is inversely proportional to its moment of inertia. In the case of a cantilever, 1 ft. wide, cut by assumed vertical planes from a dam, the deflection due to a given load is inversely proportional to the third power of the thickness. Then, for a cantilever with $n$ laminæ of equal thickness,

and assuming further the total load to be equally divided between the $n$ laminæ, the deflection of each lamina is increased by $\frac{n^3}{n} = n^2$. In other words, the deflection of the laminated cantilever is increased by the square of the number of laminations. Consequently, the cantilever elements of laminated arch dams will be more flexible and the bending moments at the base of the cantilevers which in a monolithic dam would be likely to produce cracks between the dam and the foundation at the up-stream face, are greatly reduced. Furthermore, each cantilever element will be bent individually, thus giving a better stress distribution upon the foundation than in a monolithic structure.

The laminating slightly increases the deflection of the arches. The deflection of the vertical elements is increased in proportion to the square of the number of laminations. A greater proportion of the load, therefore, is thrown upon the arches, especially near the base of a dam; this is desirable because it increases the efficiency of arch action.

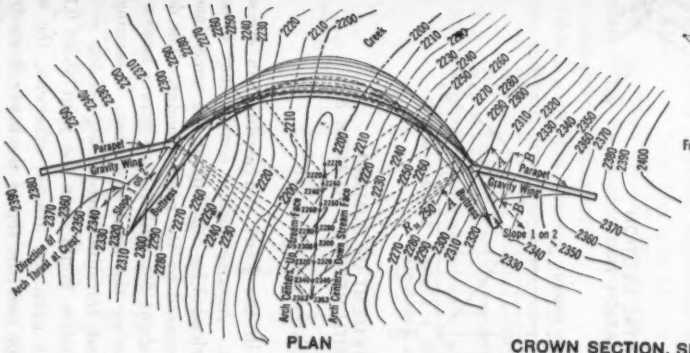
The effectiveness of laminating the arches of thick arch dams is evident from the following considerations. Suppose it were practicable to subdivide an arch dam having a radius of 100 ft. into a number of very thin concentric arch laminæ, say, 1 ft. in thickness, each. The dam would then be composed of extremely thin arch rings for which the cylinder formula would be applicable with a relatively small percentage of error. The vertical cantilever elements would be so thin and flexible that they would probably carry only a very small percentage of the load except in the immediate vicinity of the foundation. The cylinder formula, therefore, would be approximately valid for such a structure and the water pressure would be transmitted to the arch abutments by a practically uniform axial compression in the thin arch laminæ. From the theoretical point of view this would result in maximum efficiency, and for a given allowable unit stress would require a minimum of concrete. In practice, this ideal, of course, can not be attained, but it can be approached by providing a reasonable number of laminations.

It is evident that the principle of laminating arch dams may be applied also to arches which increase in thickness toward the abutments as well as to arches of uniform thickness between abutments. In fact, arches which are thicker at the abutments will be most economical, because the critical stress is generally at that point.

There are several ways to provide joints for laminations without unduly increasing the unit prices of the concrete of the arch. For instance, the arch on the down-stream side of the joint may be built one lift, say, 5 ft., higher than the adjacent up-stream arch; the up-stream forms of the higher arch may then be removed, and the face painted with asphalt or some other suitable material to prevent bond across the joint. Then, the up-stream lamina is poured directly against the face of concrete so treated.

Instead of a coating of asphalt the up-stream face of the down-stream lamina may be provided with a water-proofing membrane, thus giving reasonable assurance that no water will seep through to the down-stream face of

the dam. By placing split drain pipes against the membrane at suitable intervals of, say, 20 to 40 ft., any water seeping through the up-stream arch lamina may be drained off readily.



A simple method of producing a cold joint between the arch laminæ, would be to place and securely hold in position, a continuous sheet of impregnated burlap or elastite and then pour concrete on both sides of the sheet. This will provide a joint, at a minimum interference with concreting.

It is important that the lamination of an arch dam be arranged so that the highest lamina is at the up-stream side of the dam. The other laminæ are placed in steps down stream from the first lamina. The laminæ are not connected with each other, except possibly along the foundation. Any water that might seep from the reservoir through the first arch into the joints between the laminæ, can easily be drained away, if desired. One may also choose to permit a film of water to accumulate in the joints between the different arch laminæ so that each lamina would be subjected to a definite hydrostatic pressure. Any surplus water in the joints would be likely to escape from them over the tops of the different laminæ, or could be drained in a lateral direction at any desired elevation toward the arch abutments. In any case, it is quite obvious that none of the individual arch laminæ could ever be overstressed by excessive hydrostatic pressure in a joint.

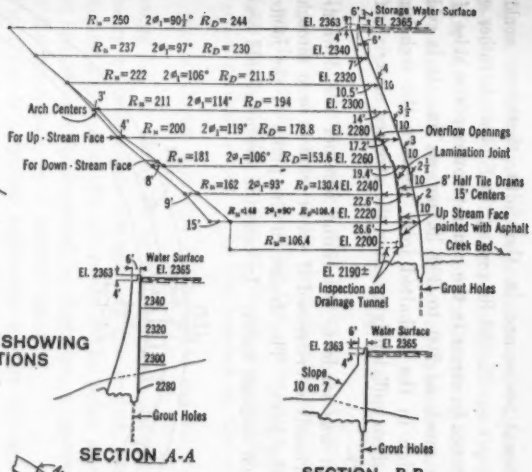


Fig. 7 shows the plan, elevation, and cross-sections of a laminated cone arch dam proposed to be built for an irrigation project in California. In order to insure positive and unfailing action of the drainage system in the joint between the arch laminæ a number of overflow openings are provided along the top of the lower arch lamina. Water rising in the joint to the top of the laminæ would immediately drain off and thus prevent the lower arch lamina from being subjected to excessive hydrostatic pressure. In addition to these overflow openings, drains are provided in the joint leading to an inspection and drainage tunnel extending along the foundation of the arch. From this inspection tunnel the vertical drains in the joint may be opened up, if necessary. Thus, there is no possibility of the down-stream arch lamina ever becoming overloaded through clogging of the drains.

The factor of safety of a laminated arch dam can be ascertained by model tests in a relatively simple manner by loading each arch lamina of the model separately to the point of breaking. The difficulty and expense of securing sufficient static pressure to produce failure of each arch lamina separately, are evidently much smaller than if a model of the complete dam were tested to destruction.

An investigation was made to determine whether the friction in the asphalted joint might prevent the sliding of the arch laminæ upon each other, thus defeating to some extent the purpose of laminating. Assume an elementary horizontal arch with two arch laminæ at a depth of 200 ft. below the crest of a dam. The water pressure at this depth is $62.5 \times 200 = 12\,500$ lb. per sq. ft. The up-stream lamina is assumed to carry one-half this pressure, the other half (6 250 lb. per sq. ft.) being transmitted across the joint to the down-stream lamina. Assuming a coefficient of friction in the asphalted

Showing Reinforcement of Arch-Abutment Monolith

FIG. 7.—PLAN AND SECTIONS OF DAM NO. 2.

joint of 0.5, the frictional resistance in the joint, therefore, would be $0.5 \times 6\,250 = 3\,125$ lb. per sq. ft. (22 lb. per sq. in.) This is rather small as compared to the difference in stress in the concrete on opposite sides of the joint, which may be as much as 200 to 300 lb. per sq. in. It is evident, therefore, that the friction in the asphalted joint between the arch laminæ is not likely to restrain them sufficiently to alter the stresses materially from those indicated by theory.

Another investigation was made to determine whether the down-stream arch lamina could be seriously overstressed if water were to seep through the up-stream lamina into the joint. The drains in the plane of the joints are provided to carry off such seepage water. In case the drains should cease to

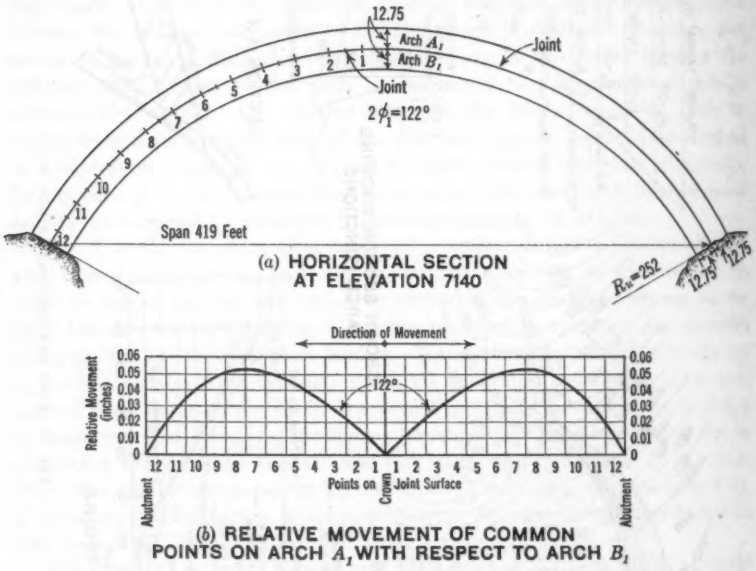

FIG. 8.—TYPICAL ARCH OF DAM NO. 1.

function, water might accumulate in the joint and produce an excess of pressure on the down-stream lamina. Assume such a contingency to occur. The down-stream arch might be overloaded by 5%, but at the same time the load upon the up-stream arch is decreased by the same amount. The down-stream lamina will deflect more by about 5% and the up-stream lamina will recede by the same amount, thus opening the joint somewhat. Assuming the arches to deflect 1 in. under full load, the difference of 5% + 5% = 10% of the deflection of the two arch laminæ would open the joint about 0.1 in. This would probably be sufficient to open the drains; otherwise, the water in the joint would undoubtedly escape over the top of the lower down-stream lamina thus reducing the loads of the two laminæ again to normal conditions.

In case of differences of the temperature of the up-stream and down-stream laminæ the dam would not be any worse off than a monolithic arch. In fact, grouting of the vertical joints of the laminæ with different pressures would afford a convenient means for correcting subsequent influences of temperature variations.

### Determination of Maximum Arch Thickness

The maximum allowable arch thickness, and hence the number of laminations required at any elevation, depends, of course, on the design assumptions and working stresses. Assuming the preliminary design to be based on a uniform stress of 350 lb. per sq. in. by the cylinder formula, and assuming the actual critical stress to be the tension at the abutment, it is indicated that the maximum uniform thickness is reached when $\frac{t}{r}$ is about 0.15, assuming $2\phi_1$ at about 90 to 100 degrees. Recourse to laminating is not necessary at this point, however, as the critical stress can be reduced by thickening the arch at the abutment. The point at which the first or subsequent laminations are required, is, therefore, a matter of judgment dependent upon the conditions, to a certain extent.

Fig. 8 (*a*) is a typical horizontal section through the dam shown in Fig. 5 at Elevation 7 140. The arch at this elevation is thicker at the abutments than at the crown, but in order to simplify the computations for the present purpose, it will be assumed that the arch laminæ are of uniform thickness from abutment to abutment.

Table 2 gives the stresses at the crown and abutments in the two arch laminæ and, by way of comparison, also in the unlaminated arch.

TABLE 2.—Comparison of Arch Stresses.

| Arch. (see Fig. 8.) | Arch thickness, $t$, in feet. | Radius at center line, $r$, in feet. | $\frac{t}{r}$. | Central angle, $2\phi_1$, in degrees. | Arch Stresses, in Pounds per Square Inch. | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | Cylinder. | Rib-Shortening. | | Cylinder Plus Rib-shortening. | | 10° Drop of Temperature. | | Total for Load and Temperature. | |
| | | | | | | Crown. | Abutment. | Crown. | Abutment. | Crown. | Abutment. | Crown. | Abutment. |
| (1) | (2) | (3) | (4) | (5) | (6) | (7) | (8) | (9) | (10) | (11) | (12) | (13) | (14) |
| $A_1$, Extrados..... | 12.75 | 245.6 | 0.052 | 122 | 429 | 64 | −129 | 493 | 300 | 25 | −50 | 518 | 250 |
| $A_1$, Intrados..... | 12.75 | 245.6 | 0.052 | 122 | 429 | − 70 | 125 | 359 | 554 | −27 | 48 | 332 | 602 |
| $A_2$, Extrados..... | 12.75 | 232.9 | 0.055 | 122 | 429 | 67 | −135 | 496 | 294 | 26 | −52 | 522 | 242 |
| $A_2$, Intrados..... | 12.75 | 232.9 | 0.055 | 122 | 429 | − 75 | 131 | 354 | 560 | −29 | 50 | 325 | 610 |
| Monolith, extrados. | 25.50 | 239.3 | 0.106 | 122 | 429 | 114 | −249 | 543 | 180 | 44 | −96 | 587 | 84 |
| Monolith, intrados. | 25.50 | 239.3 | 0.106 | 122 | 429 | −140 | 232 | 289 | 661 | −54 | 89 | 235 | 750 |

From the values given in Column (14) of Table 2, it is seen that in the arch under consideration the maximum stress at the abutment intrados is

610 lb. per sq. in. in the laminated arch, while in the monolithic arch the maximum stress at the same point would be 750 lb. per sq. in. The process of laminating this arch reduces the maximum stress at the abutments by 140 lb. per sq. in., which is between 20 and 25% in favor of the laminated arch. For laminated arches of non-uniform thickness the reduction in stress, or the economy of material in case of the same size of maximum stress that may be obtained by laminating, is generally about in the same proportion as for arches of uniform thickness, such as those considered in the preceding example.

Fig. 8(*b*) gives the movement of Arch $A_1$, relative to the arch, $A_2$, in the plane of the joint between the two arches, due to a change of water pressure from no load to full load. For this purpose the stresses and corresponding strains at the intrados of Arch $A$, and at the corresponding points across the joint, at the extrados of Arch $A_2$ were calculated and the elastic deformations at the arch surfaces added from abutment to abutment. A modulus of elasticity of 3 000 000 lb. per sq. in. was used in the computations.

Each arch was divided into twenty-four sections of equal length, and the stresses were computed on radial sections through the center of these lengths, as indicated by the numbered points in the diagram. The stresses thus found were assumed to be the average for each increment, $\Delta S$, of length, and the deformation computed accordingly, on the intrados of Arch $A$, and the extrados of Arch $B$. Beginning at the abutment, these deformations for each arch were progressively added. The difference in these sums, for any point, gives the movement of this point on the intrados of Arch $A$ with respect to the same point on the extrados of Arch $B$, which is shown graphically in the diagram.

Thus, for a laminated arch of the shape and dimensions shown in Fig. 8(*a*) subjected to stresses, as given in Table 2, the maximum relative movement of the two arches in the plane of the joint would be about 0.05 in. This is very little and may take place in an asphalted joint without difficulty. The maximum sliding movement in the joint of 0.05 in. will occur only in case of a change from no load to full load conditions, or *vice versa*, and accompanied by a change of temperature corresponding to that assumed in Table 2. For most dams, such conditions obtain not oftener than once or twice each year.

### French Dam Utilizing Principle of Lamination

In connection with the writer's proposed lamination of thick arch dams, an account of a high dam under construction in France, in which the same principle has been utilized, should be of interest. Since this structure represents such a bold departure from precedent it is believed that a fairly complete description will be in order.

The dam is at Marège, on the Dordogne River, in France.[11] The lamination is effected in a rather different way from that proposed by the writer, but the purpose in view, and except for slight differences, the general structural effects are essentially the same. The dam, as shown in Fig. 9, will be

[11] *Revue Générale de l'Electricité*, October 29, 1927.

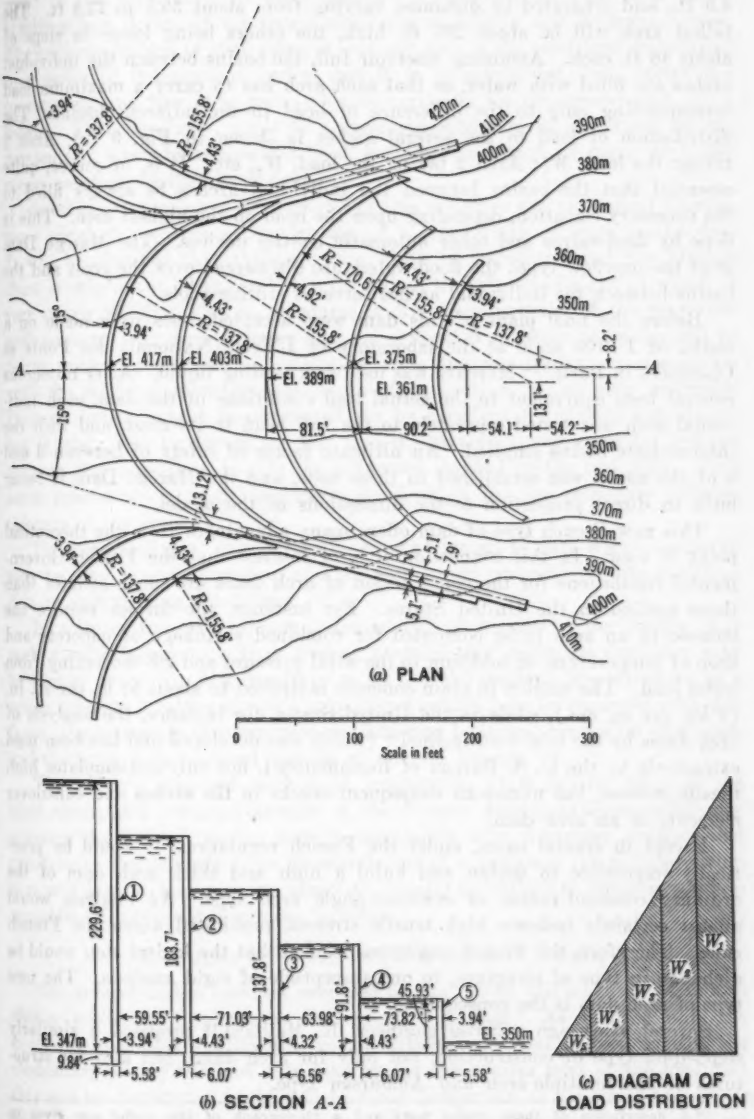

FIG. 9.—DORDOGNE RIVER DAM AT MARÈGE, FRANCE, PLAN AND SECTIONS.

composed of five thin arches of reinforced concrete, the thickest being only 4.9 ft., and separated by distances varying from about 59.5 to 73.8 ft. The tallest arch will be about 230 ft. high, the others being lower in steps of about 46 ft. each. Assuming reservoir full, the basins between the individual arches are filled with water, so that each arch has to carry a maximum load corresponding only to the difference of head in the adjacent basins. The distribution of load to the several arches is shown in Fig. 9 (*c*), Arch 1 taking the load, $W_1$; Arch 2 taking the load, $W_2$, etc. It is, of course, quite essential that the basins between the individual arches be always filled to the necessary elevation, depending upon the head on the highest arch. This is done by float-valves and other automatic control devices. The Marège Dam is of the overflow type; the flood-waters are discharged over the crest and the basins between the individual arches serve as stilling-pools.

Before the final plans of this dam were accepted, tests were made on a model of 1 : 100 scale at the laboratory of L'Ecole Nationale des Ponts et Chaussées in Paris.[12] Mercury was used as a loading liquid. After numerous general tests equivalent to the actual load conditions of the dam, each individual arch was tested separately to the full head to its crest, and with the intermediate basins emptied. An ultimate factor of safety of between 3 and 4 of the model was established in these tests, and the Marège Dam is being built in direct proportion to the dimensions of the model.

This new French type of dam offers many advantages from the theoretical point of view. In this connection it is of interest that the French Governmental regulations for the construction of arch dams are much stricter than those applied in the United States. For instance, the former require the stresses in an arch to be computed for combined shrinkage of concrete and drop of temperature, in addition to the axial pressure and rib-shortening from water load. The tension in plain concrete is limited to about 52 lb. per sq. in. (4 kg. per sq. cm.), while in the United States, for instance, the analysis of arch dams by the trial-load method[13] (which was developed and has been used extensively by the U. S. Bureau of Reclamation), not only contemplates high tensile stresses, but numerous consequent cracks in the arches and cantilever elements of an arch dam.

Except in special cases, under the French regulations it would be practically impossible to design and build a high and thick arch dam of the ordinary constant-radius or constant-angle arch type. An analysis would almost certainly indicate high tensile stresses, prohibited under the French rules. Therefore, the French engineers decided that the logical step would be a change in type of structure, to one susceptible of rigid analysis. The new type of arch dam is the consequence.

Several years ago a Swiss engineer, R. Maillard,[14] proposed a similarly stepped-off type of construction, not only for arch dams, but also for structures of the multiple-arch and Ambursen type.

[12] A description of these model tests and a photograph of the model are given in *La Revue Industrielle*, July, 1927, p. 340; see, also, *Engineering News-Record*, August 30, 1928, p. 311, and *Western Construction News*, July 25, 1928, p. 465.

[13] "Analysis of Arch Dams by the Trial-Load Method," by C. H. Howell, M. Am. Soc. C. E., and the late A. C. Jaquith, Esq., *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1191.

[14] *Schweizerische Bauzeitung*, April 14, 1928, p. 183.

The Swiss and French designs probably represent the ultimate attainment in the application of pure logic to the problem of high arch dams, resulting in a design of maximum structural simplicity and determinateness. The striking feature of their plan is that not only is the total load distributed to a series of independent arches, but it is so subdivided that, except the lowest arch, each one is uniformly loaded vertically for the greater part of its height. This, obviously, tends to a great simplification of structural action, particularly when buttresses are used, keeping the length of many arch elements constant, as they have done.

Another outstanding characteristic of this design is the very small foundations which it requires, except in case of a great depth of loose overburden. It will be observed that the aggregate width of foundations of the Marège Dam is only about 30 ft., and this for a dam the effective height of which is very nearly 230 ft. This is, of course, a direct consequence of the very thin arch sections, and the assurance that the vertical foundation reactions will be fairly uniformly distributed. Judging from the topography, in connection with the sectional elevation, the depth of excavation is also very moderate. This, of course, might be accounted for by excellent foundation conditions, but it might also be due to the fact that the maximum argument for leakage through the foundation is only the difference in head on the two sides. This same consideration is an important justification for the relatively extreme thinness of the arches.

The adaptability of this particular type of layout to dam sites in general, may be open to some question, and the plan would probably require modification to suit varying conditions.

In spite of the great apparent theoretical advantages of the design, it is such a radical departure from present practice that engineers elsewhere may be slow to adopt it. Also, contrary to its actual functions, the structure as a whole presents a rather complex appearance, which may be regarded with disfavor; the extremely thin concrete sections may be looked upon with suspicion, and the form work required may be an adverse feature.

The writer's proposed method of lamination, while falling short of the ideal theoretical accomplishments of the French design, perhaps sufficiently achieves the desired results, more harmoniously with American practice and conditions. Particularly from the standpoint of appearance, the finished structure will seem to be a massive monolith, similar in outline to structures representative of advanced American practice.

## Reduction of Cantilever Influence in Design

The several design features proposed by the writer will make it possible to obtain relatively thin arches throughout the dam. As pointed out, the cantilever elements will become comparatively ineffectual. Consequently, the elementary arches will not only take by far the greater part of the load, but this will be distributed fairly well in direct proportion to the water pressures; that is, horizontal elementary arches would carry approximately a uniform radial load. The reason for dividing the total load between arches and the cantilevers, in the case of thick arches, is not merely because this produces

refinements of design from the standpoint of economy, but because the cantilever action may result in more unfavorable conditions than if they were absent. In other words, if the cantilever action were neglected, not only would the resulting analysis be entirely erroneous, but it might be actually unsafe. Evidently, the thicker the arch the greater the necessity for considering cantilever action; conversely, the thinner the arch, the greater the assurance that this may be omitted without jeopardizing the safety of the analysis, which will at least approach the actual conditions. While the writer does not favor discarding any proper refinements of analysis, it is believed that in the proposed design, the elementary arches might be assumed to carry the entire water pressure, and yet give essentially the same dimensions of structure as if the cantilevers were considered. At least, the preliminary design would require the minimum of subsequent modification. The design, of course, may be checked and altered if necessary, by the trial-load method,[15] investigating a suitable number and combination of elementary cantilever and arch elements.

To avoid an undesirable reversal of stress at the base of the dam, and to make the action of the vertical elements more determinate, a temporary hinge may be provided during construction, and later grouted, as recommended[16] by Victor H. Cochrane, M. Am. Soc. C. E. This, of course, would tend to diminish the cantilever action even more.

## The Railroad Canyon Cone Arch Dam

As an example of the actual application of the design principles proposed by the writer (except that of lamination), there follows a description of the Railroad Canyon (cone arch) Dam, built in 1927-28, on the San Jacinto River, near Elsinore, Calif. (See Figs. 10 and 11.) The height and layout of the dam were such that laminations were not required. The properties of this design, except laminations, are generally the same as those that have been described and discussed in detail in connection with the typical design, Fig. 5.

The dam is of the overflow type, the spillway over the central portion of the crest being designed for 30 000 sec-ft. The maximum recorded flood at the site is 15 000 sec-ft. The crest overflow will be spilled into a stilling-pool formed by a small arch, 20 ft. high, built about 50 ft. below the dam. (See Fig. 10.) Except immediately adjacent to the crest and the base, the crown slope is 10:4, which gave a layout suitable to the topography.

Those portions of the arches adjoining the abutments, and also both forks of the abutments were strongly tied together with 1¼-in. round reinforcing bars. The buttress was designed to take the computed arch thrust, but, as previously stated, it seems evident that failure could occur only by the simultaneous crushing or sliding of both the buttresses and the wing-wall. This affords a very large safety factor, over and above that provided in the design.

The highest axial stresses in the horizontal arches due to the water pressure are about 360 lb. per sq. in. The arches are of uniform thickness at the upper elevations, but are thickened toward the abutments, in the lower portion

[15] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1191.

[16] *Loc. cit.*, Vol. LXXXVII (1924), p. 378.

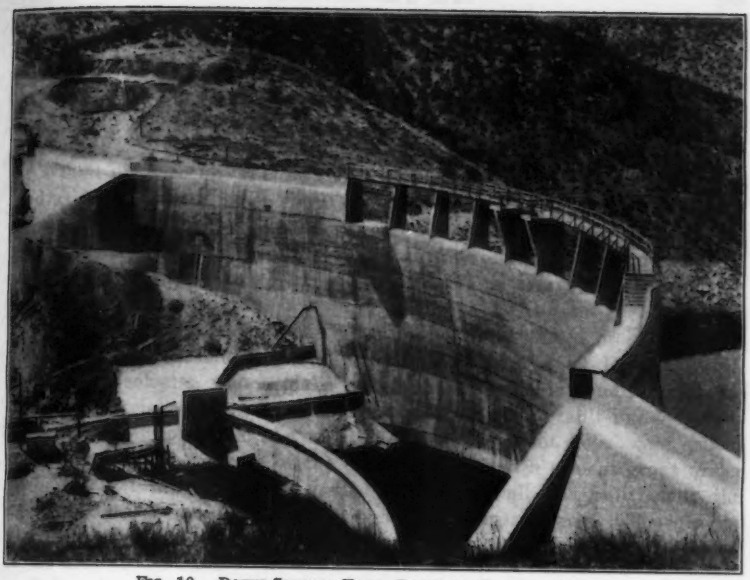

FIG. 10.—DOWN-STREAM FACE, RAILROAD CANYON DAM.

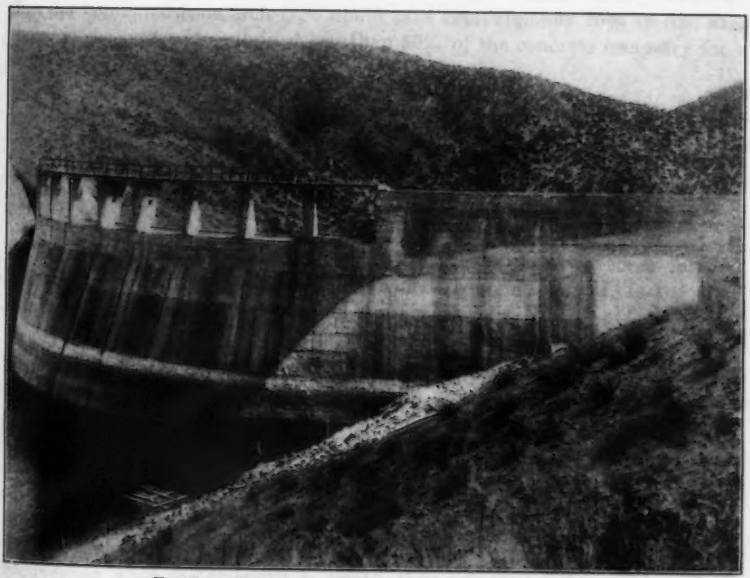

FIG. 11.—UP-STREAM FACE, RAILROAD CANYON DAM.

of the dam. In the design, the maximum allowable compression was taken at 600 lb. per sq. in., and the maximum tension at 100 lb. per sq. in., including the stresses due to rib-shortening, which are the limits set by the State Engineer of California.

The bed-rock at the dam site is slate. In the bottom of the canyon and for a short distance upward the rock is extremely hard, in places almost as hard as flint. At the upper elevations it is softer and fractured into small pieces. Where the shattered rock was encountered the excavation was varied to a maximum of 35 ft. below the original surface of the ground, and the concrete abutments of the arch were widened to give an average pressure on the rock of about 10 tons per sq. ft.

A fault line in, and approximately parallel to, the river bed, crosses the dam site, but this is considered "dead" in an opinion given by Roy G. Mead, Consulting Geologist, who made a report on the geologic conditions at the dam site. Special care was taken in the excavation at the fault line by grouting and deep cut-off work. In addition, numerous grout holes were drilled into the rock below the base of the dam, and filled with cement grout under pressures of about 100 lb. per sq. in. A cut-off wall was built along the up-stream face of the dam for further safety against seepage. The gravity wing-walls were designed for the hydrostatic head assumed to act over 50% of the area of the base.

Before deciding upon the dam for this location, comparative designs and estimates of cost were made for five types of dams. These studies indicated that the laminated cone arch type would save approximately 20% in cost over the next cheapest. It contained less than 50% of the concrete necessary for a straight gravity dam.

## Acknowledgments

The writer is indebted to S. M. Cotten, M. Am. Soc. C. E., for valuable aid in the preparation of this paper.

## Conclusions

The type of arch dam described in this paper involves three features which promote both simplicity of design and economy, namely, forked abutments, sloping crown of the arch, and laminations:

(1) The so-called "forked abutments" take the thrust of the upper portions of the arch. Each abutment consists of a buttress and a gravity wing-wall poured integrally, thereby forming an arch abutment of large cross-section and great resistance to shearing, overturning, and sliding. The forked abutments reduce the span of the arch and permit the use of relatively short arch radii and a correspondingly small thickness of the arch.

(2) A pronounced sloping of the crown of the arch, secures short radii and large central angles for the arch elements below the crest. The small overhang of the arch in the center will keep the upper arch elements under light compression when the reservoir is empty, thus preventing the opening of the construction joints.

(3) The sub-division of the total arch thickness into two or more arch laminæ, keeps the arches relatively "thin" and reduces greatly the cantilever action so that the arch elements are more nearly uniformly loaded and may be designed without recourse to complicated methods of arch analysis.

These three features may be used to advantage either singly, in combinations of two, or all three of them, in the design and construction of arch dams at most sites. The resulting structures will involve arches of high efficiency, subject to simple, but nevertheless comparatively rigid analysis. The forked abutments are structural elements with a high degree of design and reserve strength. They can be arranged at many sites in such a way that they improve greatly the conditions as to span, symmetry, and economy of the main portion of the structure, namely, the arch.

## DISCUSSION

LARS R. JORGENSEN,[17] M. AM. SOC. C. E. (by letter).—At and toward the bottom of a high arch dam in a narrow canyon the arch action is inefficient, and the dam has much greater stability as a plug, if the excavation is shaped in such a way that shear parallel to the side-hill can be resisted. The concrete has a very large shearing resistance and it is just as well to take advantage of this.

For fairly thin arch dams the writer would prefer to keep the arch solid in order to preserve full shearing strength in the concrete in all directions. Some difficulties may also arise in getting the laminations to slide on one another, and, moreover, this type of construction increases the form work.

A single trial calculation of the unit shear in the lower portion of a thick arch dam in a narrow canyon will, in general, disclose average shearing stresses along the contact area with rock of less than 100 lb. per sq. in., the assumption being that the plug carries full water pressure. The load is actually divided between arch action and punching shear and since the former is inefficient in this zone, most of the load is carried by punching shear, and it is evident that as long as the unit punching shear is low, the thick arch portion cannot fail. While the shear is normally not uniformly distributed over the contact area, it is believed that some time before failure it will be so distributed.

The ultimate shearing strength of concrete in the lower part of a high arch dam should not be less than 2 000 lb. per sq. in. for good concrete, especially since some arch compression acts more or less perpendicular to the plane of shear. A high dam in a narrow canyon should always be investigated for punching shear in its lower portion because that, rather than arch action, is really what supports most of the load. However, it does not make any difference how a dam is held in place as long as it remains there with a sufficient factor of safety.

To overhang the crown of an arch down stream is a practical way to obtain minimum length of radii for the lower arch elements. This can be secured to a still higher degree by overhanging the dam on the up-stream side of the abutments as well. Several such dams have been built and are projected.

Such a dam, however, is not a cone dam; both the up-stream and down-stream faces are warped. Merely to incline the dam in the middle does not produce conical surfaces at any place. Fig. 5 shows plainly that the up-stream face projects a maximum at Section *B-B*, and that this projection diminishes toward the abutments where it may become zero or negative. The axis on which the centers lie is not a straight line in any plane and therefore neither face could be a cone as described by the author.

The author states that "the arches are of uniform thickness at the upper elevations, but are thickened toward the abutments, in the lower portion of the dam." That feature does not make a conical surface out of it. Both faces

[17] Cons. Hydro-Elec. Engr., San Francisco, Calif.

of this dam are warped in a way that is characteristic of the "constant angle arch" type of dam.

In 1911, the writer gave the type of dam shown in all the illustrations this name. It seemed the best available, in order to emphasize that the important thing was to keep the subtended angle constant and large at all elevations. While the lengths of the radii are variable from crest to foundation, this is not a characteristic but an incident; this fact was the main reason for not giving the name of, say, "variable radius" arch dam.

The Railroad Canyon Dam shown on Fig. 10 and Fig. 11, appears to be of the same type and the only new feature on this design is the forked abutments.

It is very possible to construct an arch dam in a V-shaped canyon, such that the up-stream and down-stream faces would be inverted cones. Such a structure could rightly be called a cone arch dam; but it seldom would be practical. Figs. 5 and 7 have warped surfaces and are circular, or nearly circular, in horizontal planes, but they are not cone-shaped arches.

WILLIAM CAIN,[18] M. AM. SOC. C. E. (by letter).—The main object in the proposal of the use of the laminated arch dam, as defined by Mr. Noetzli, is to substitute a series of "thin arches", properly combined, for the "thick arch" as usually constructed. The theory of the thick horizontal arch under uniform normal loads and temperature changes, has been developed by B. F. Jakobsen, M. Am. Soc. C. E.[19] the writer, in his discussion,[20] giving an independent analysis of the problem. The application to actual structures often shows that so much tension is exerted at certain points—the extrados at the abutments and the intrados at the crown—that numerous cracks will form there, so that it is proposed to ignore this part of the primary arch that is in too much tension and to substitute for it a so-called "secondary arch". The effect is to place in the dam material that is structurally inoperative, which, Mr. Noetzli claims, is poor design.

The advantage of the laminated dam is that the corresponding theory is much simpler—approaching that of the "cylinder theory"—but it must be borne in mind that even for the thin arch, cracks are to be expected (as witness the many cracks experienced in the Stevenson Creek Experimental Dam[21]), so that the theory that supposes no cracks to form, is again not strictly applicable, even for the thin dam.

In the Stevenson Creek Experimental Dam, cracks occur at parts of the base and at the side walls of the canyon, as well as at other points; so that the dam cannot be regarded as "fixed" over such parts of the base or side walls where cracks occurred. Further, for the upper part of the dam, the arches were deflected down stream for the central portion and up stream for parts nearer the abutments, so that no existing theory applies for much of the dam.

[18] Prof. Emeritus, Univ. of North Carolina, Chapel Hill, N. C. Professor Cain died December 6, 1930.

[21] *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3.

In the theory best known, the dam is considered artificially divided into a series of horizontal arches and vertical cantilevers and the shear between them is neglected, whereas the true solution would be to consider the arched dam as a whole, including the shear, to which the strict theory of elasticity should be applied for a solution. When this is done, doubtless many surprises are to be looked for, because the results will hardly agree with present approximate solutions, especially if the analysis, as usual, proceeds on the hypothesis of no cracks or the dam remaining intact.

The trial-load method has been applied, assuming the usual artificial division of the dam into arches and cantilevers, ignoring the shear between them, and, in addition, regarding as operative only those parts of the sections on which no tension is exerted. This necessarily leads to inexact results, for plain concrete can take a certain amount of tension—possibly 100 lb. per sq. in. or less. The result would also be inexact if the dam is supposed to remain intact and thus to be able to resist whatever tension would be exerted.

On all these accounts, the problem is seen to be very complex, so that any device that would lead to a simpler approximate solution, should prove welcome. This has been attempted by Mr. Noetzli in his so-called laminated dam, built up by a series of thin dams, to which the theory of thin arches applies, so that the solution, as the thickness of the arch diminishes, approaches that of the cylinder theory. Another great advantage is that the stiff, thick cantilevers of the thick arch, are replaced by thin, flexible cantilevers, which carry very little load, most of it being transferred to the horizontal arches. On that account, possibly the very laborious trial-load method can be omitted and a uniform normal load on the horizontal arches assumed, for which the theory is comparatively simple.

The author further proposes the use of forked abutments, which should give a very stiff structure and thus ensure that the arches are practically "fixed at the ends", and that shorter spans and more favorable radii will result. There are also other advantages, to which the author calls attention, in the proposed sloping of the crown of the arch. It is a question likewise as to whether the arch dam should not be constructed with vertical radial joints, at intervals, to be subsequently grouted at low temperatures, and also whether the cantilevers should not be simply supported (or hinged) at the base, so as to throw as much of the load as possible on the arches. The writer has given the solution for the latter case as applicable to the Wooling Dam,[22] using the method[23] of B. A. Smith, M. Am. Soc. C. E.

The formulas and diagrams for the computation of the stresses in the thin horizontal arches are based on the writer's theory for the thin arch.[24] For example, the total tangential stress at the point $(r, \phi)$ is:[25]

$$P = p\,r - (p\,r - P_0)\cos\phi = p\,r - R_r\cos\phi \ldots\ldots\ldots (9)$$

[22] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 311.

[23] *Loc. cit.*, Vol. LXXXIII (1919–20), p. 2027.

[24] "The Circular Arch Under Normal Loads," *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 233.

[25] *Loc. cit.*, p. 236, Equation (4).

Dividing Equation (9) by 144 $t$, the result is the total rib-shortening stress, in pounds per square inch. In this equation, the first term, $\frac{p\,r}{144\,t} = \frac{p'\,R_s}{144\,t'}$ gives the cylinder stress, $\sigma_c$, of the author's Equation (2); the second term, $-\frac{H_r \cos\phi}{144\,t}$, gives the stress due to the pull, $H_r$, at the crown, tending to lengthen the neutral axis. The algebraic sum gives the total rib-shortening stress.

Assume, for convenience, that $y = \left(\frac{\sin\phi_1}{\phi_1} - \cos\phi\right)$; then the moment at $(r, \phi)$ is:[24]

$$M = R_r\,r\,y \qquad (10)$$

so that the stress due to this moment at the intrados or the extrados, in pounds per square inch, is:

$$\frac{1}{144}\,\frac{6\,M}{t^2} = \frac{1}{24}\,\frac{H_r\,r\,y}{t^2} \qquad (11)$$

Hence, the stress at intrados or extrados, due to the pull, $H_r$, and the moment is,

$$\sigma_r = -\frac{H_r \cos\phi}{144\,t} \pm \frac{H_r\,y\,r}{24\,t^2}$$

This is the author's Equation (5),[26] in which $\phi = 0$ at the crown and $\phi = \phi_1$ at the abutment. The total unit stress, is thus, $\sigma = \sigma_r + \sigma_c$, as in the author's Equation (8).

Similarly, the results for temperature changes are derived for the free arch, not including the effect of the restraint due to cantilever action. The formula given for $\sigma_r$ is not the rib-shortening stress, which is strictly,

$$\sigma = \frac{H_r \cos\phi}{144\,t} \qquad (12)$$

and is uniform over the section of thickness, $t$.

The author gives in Fig. 9, a plan of a French dam consisting of five, thin, reinforced arches, placed one below the other, 60 ft. or more apart, the heights decreasing down stream. The principle of lamination is well illustrated in the design which has many advantages and some disadvantages. As to the latter, the extra form work is objectionable, and possibly the arches are not fixed at the abutments so well as in the author's design. His laminated arch is very interesting, and it is to be hoped that it will be fully tested in an actual construction.

B. F. JAKOBSEN,[27] M. AM. SOC. C. E. (by letter).—The "laminated cone arch dam" appears to be a constant-angle arch dam,[28] provided with one or more asphalt-covered slip-joints, which are concentric with the up-stream face of the dam. These joints are assumed to permit minute movements and adjustments between the separate arch sections. The author is so certain that this

[26] "The Circular Arch Under Normal Loads," *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 237, Equation (13).

[27] Cons. Engr., Los Angeles, Calif.

[28] "The Constant-Angle Arch Dam," by L. R. Jorgensen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 685.

must happen, that he suggests a test of the factor of safety be made by loading each arch lamina of a model separately. That process amounts to taking for granted just what is most in need of proof, namely, whether or not these slip-joints, the areas of which must be measured in acres, will function as assumed. A test on a model would give no reliable information as to whether or not several acres of asphalt-painted surfaces will slide more or less freely on each other; furthermore, it would give no information as to how aging, temperature variations, etc., would affect the coefficient of friction. The proposed design has no application to small structures, since there is no decided advantage in laminating the arch unless it is quite thick. For comparison, it may be stated that the up-stream face of the proposed San Gabriel Dam of the Los Angeles County Flood Control District, has a surface area of more than 20 acres.

The author refers to the successful testing of the Stevenson Creek Arch Dam and suggests that a simple test on a small model would furnish the factor of safety of his proposed design. A comparison of the design data for the Stevenson Creek Dam with the test data, and the values obtained from the celluloid model, suggests caution rather than confidence.[29] There appear to be too many factors which the model may not reproduce correctly, but which would affect the safety of the structure.

Mr. Noetzli assumes a coefficient of friction of 0.5 for the asphalt-painted joints. This may be a fair assumption under ideal conditions, for small areas, while the asphalt is fresh and its temperature not too low; but such ideal conditions, involving practically true surfaces, as in a machined joint, will not be obtainable in large dams. Furthermore, the effect of shrinkage, swelling, temperature variations, etc., will warp these surfaces, and the total result is likely to be high compression between the two surfaces at various points and no compression at other points. This will tend to increase the frictional resistance.

The friction here involved is that of rest following a considerable period of no movement, during which time the surfaces have been pressed tightly together, and the movements are minute, as stated by the author. These are the conditions most unfavorable for a small coefficient of friction.

The writer is not able to follow the author's calculations of the influence of friction, but if any friction whatever exists, it will defeat the purpose of the lamination to some extent. It is also clear that there will be no movement at all, where the shear is less than the product of compression between the surfaces and the coefficient of friction. That the average shear for the whole surface is greater than the average frictional resistance, will hardly suffice, because relatively small movements at places where there is an excess of shear will materially decrease that shear. Such movements will not greatly affect the frictional resistance, because the compression between the surfaces will not be altered materially. At the crown section the shear is zero and the compression is considerable; there is no need for motion between the surfaces right at the crown section; but immediately outside, a relative movement is required and the shear is still very small.

[29] *Proceedings*, Am. Soc. C. E., May, 1929, Papers and Discussions, p. 1241.

As an actual example the writer has considered an arch with the ratio, $\frac{t}{r} = 0.5$, and the central angle, $2\phi_1 = 120$ degrees. Fig. 12(*a*) shows the radial compression, $\sigma_r$, at the crown section, where the shear is zero, Fig. 12(*b*) shows the radial compression and the shear stress, $\tau$, for the section determined by $\phi = 30°$, and Fig. 12(*c*) shows the same for $\phi = 60$ degrees. These values were calculated from the writer's paper, "Stresses in Thick Arches of Dams",[30] on the assumptions that Poisson's ratio may be neglected; that is, that $m = \infty$; that the arch carries a load of 200 ft. of water, or 87 lb. per sq. in.; and that shrinkage, swelling, temperature variations, and the yielding of the abutments are negligible. The effects of Poisson's ratio, yielding of the abutments, and swelling, are probably to increase the radial compression and to decrease the shear, while the effect of shrinkage is the reverse.

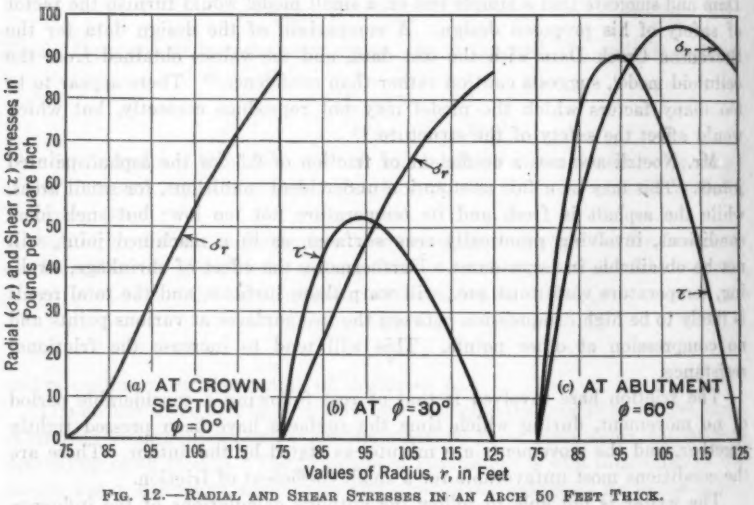

FIG. 12.—RADIAL AND SHEAR STRESSES IN AN ARCH 50 FEET THICK.

An arch 50 ft. thick would presumably be divided into three laminæ. Fig. 13 shows the values of $\sigma_r$, the radial compression, and of $\tau$, the tangential shear, at points 16.5 ft. from the up-stream face of this arch, and Fig. 14 shows the ratio of $\frac{\tau}{\sigma_r}$. Let $f$ equal the coefficient of friction; then no motion will result if $f \geq \frac{\tau}{\sigma_r}$.

For values of $f < \frac{\tau}{\sigma_r}$, motion will result (for the moment, disregarding the stresses in the cantilever), and the stresses will be partly re-adjusted. The re-adjustment will be complete only if $f = 0$. Fig. 14 shows that, for $f = 0.5$

[30] *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 475.

(as assumed by the author), $f \geqq \frac{\tau}{\sigma_r}$ from the crown section, where $\phi = 0$, to $\phi = 28$ degrees. For angles greater than $\phi = 28°$, motion and a slight re-adjustment of stresses should result. This re-adjustment will be adversely affected by the half of the arch where the shear is insufficient to produce any movement. The average value of $\frac{\tau}{\sigma_r}$ for the whole arch is about 0.483, which is less than $f$. For these reasons the writer can not accept the author's conclusion, that the friction in the joint is negligible. On the contrary, it seems, if not evident, at least highly probable, that the friction is sufficient to prevent all but very minor adjustments of the stresses, and it would also appear that this is the safe and conservative assumption.

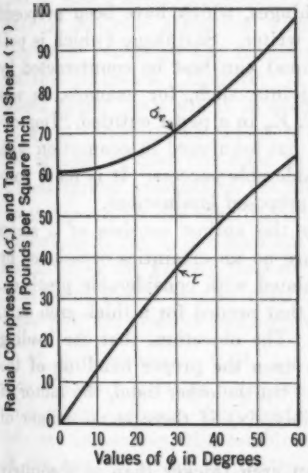

FIG. 13.—RADIAL AND SHEAR STRESSES, 16.5 FEET FROM THE UP-STREAM FACE IN AN ARCH 50 FEET THICK.

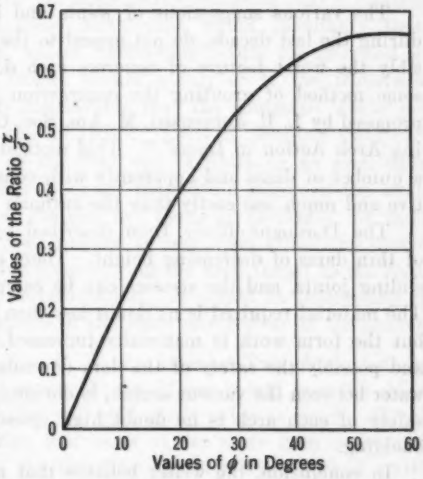

FIG. 14.—RATIO OF $\frac{\tau}{\sigma_r}$ AS DETERMINED FROM FIG. 13.

Mr. Noetzli appears to have overlooked the effect of the cantilever. The radial compression at any point in the dam is the algebraic sum of the compression due to the arch and that due to the cantilever, while the tendency to produce motion is the geometric sum of the arch and cantilever shears. As an illustration, assume arbitrarily that at any point of the arch the shear is $\tau$ and that the arch radial compression is $2\tau$. Then, if $f < 0.5$, motion will result. If, at this same point, the cantilever shear is also $\tau$ and the cantilever radial compression is $2\tau$, the incipient motion is in a direction making an angle of 45° with the horizontal; but the resulting radial compression is now $4\tau$, while the shear force tending to produce motion is $\sqrt{2}\,\tau$; their ratio is $\frac{\sqrt{2}}{4} = 0.354$ and, consequently, no motion will result, unless $f$ is less than 0.354. The influence of the cantilever is, therefore, a distinct disadvantage and it will tend to prevent motion.

The object of the theory of the secondary arch is not to determine the actual stress distribution, but to establish a limiting maximum value of the stresses, as the writer has pointed out.[31] The author is quite correct in stating that a thick arch involves inherent complexities and uncertainties; but these, the writer believes, are insignificant compared to the complexities and uncertainties involved in determining the degree of stress adjustment brought about by the laminations, because this involves everything that concerns a thick arch and a thick cantilever, with the added complications of small local movements and local stresses at the joints and the uncertainty of the coefficient of friction. These laminations, like the devices for underdraining a gravity dam, may work to some extent, and they may not; the safe assumption is that they may not function.

The various suggestions of joints and hinges, which have been proposed during the last decade, do not appeal to the writer. Shrinkage (which is possibly the worst feature of concrete arch dams) can best be counteracted by some method of grouting the contraction joints, such, for example, as was proposed by L. R. Jorgensen, M. Am. Soc. C. E., in a paper entitled, "Improving Arch Action in Dams".[32] This method has been used in connection with a number of dams and apparently with considerable success. It is more positive and much less costly than the author's proposed laminations.

The Dordogne River Dam described by the author consists of a series of thin dams of decreasing height. There are no uncertainties occasioned by sliding joints, and the stresses can be calculated with considerable precision. The material required is no doubt less than that needed for a thick arch dam, but the form work is materially increased. The objection, that the loading and possibly the safety of the dam depends upon the proper handling of the water between the various archès, is obvious. On the other hand, the factor of safety of each arch is no doubt high (possibly six) if there is no danger of buckling.

In conclusion, the writer believes that an arch thicker than is absolutely required is not an unmitigated evil nor necessarily a mere waste. The outside concrete protects the interior load-carrying portion from weathering, temperature fluctuations, and rapid drying out. In addition, if a thick arch is stressed beyond the elastic limit of the concrete at any place, a redistribution of stresses will take place, as discussed by the writer,[33] and the thick arch will be found to have a materially higher load-carrying capacity than ordinary theory indicates.

P. Wilhelm Werner,[34] Assoc. M. Am. Soc. C. E. (by letter).—The author aims at a rational use of the arch principle through application of arch lamination and of forked abutments. The views expressed in the paper are of much interest to the writer because of certain investigations made along the same lines.

[34] A. B. Vattenbyggnadsbyran, Stockholm, Sweden.

Concerning the arch lamination, the writer believes that the design, from a theoretical point of view, is a step toward the perfect arch dam. As laid out by Mr. Noetzli, the construction is also practicable and economically feasible.

As regards the forked abutments, the main question seems to be to provide for monolithic action of the abutments. In general, it is probably possible to insure safety of the abutment in regard to sliding, overturning, and other rules governing the design of a gravity section, provided the abutment could be assumed to act as a monolithic structure. In the writer's opinion it is questionable, however, whether it is possible to accomplish this with either the forked abutment or the so-called gravity tangent.

Referring to Fig. 5, the abutment of Dam No. 1 has a length of about 250 ft. and a height of about 75 ft. It is generally conceded that a straight gravity concrete structure with these dimensions would inevitably show transverse cracks in the masonry, unless contraction joints are provided at suitable intervals. However, if cracks should occur, or if the transverse joints should open up, it is easily conceivable that the abutment would not be fit to transmit the thrust to the side-hills. Even if pressure groutings are applied, it does not seem to be an ideal way of finishing an arch dam. Unless special precautions are taken to insure monolithic action of the abutments, or unless the conditions at the site are specially favorable for their construction, the writer does not feel inclined to rely upon either the forked abutment or the gravity tangent for transmitting the arch thrust to the rock. This point should receive careful consideration. It would be interesting to know how the problem has been solved in the cases referred to by the author.

H. B. MUCKLESTON,[35] M. AM. SOC. C. E. (by letter).—Two planks side by side will carry twice as much load as one plank. If one is laid over the other, with rollers between, the combination will still carry twice as much. If the two are in contact, the combination will carry rather more than twice and, if the two are clamped together, the carrying capacity will increase until, when the friction between them exceeds the longitudinal shear in a simple beam of the same depth, the combination will act as a simple beam and carry four times the load.

The author's expedient of laminating an arch dam in order to avoid the disadvantages of the thick arch will be successful according as he can avoid the frictional resistance between the laminations. This he proposes to do either by lubricating the surfaces by creating a film of asphalt, or by a physical separation of the surfaces, using hydrostatic pressure to transfer the proportionate part of the load from one lamination to the next.

The first method would be excellent provided the surfaces were truly circular in horizontal section with no departure from the true circle exceeding one-quarter, or thereabouts, of the thickness of the lubricating film. It is more than doubtful whether a large dam could be built with no departure greater than ½ in., which means that the asphalt film would be at least 2 in. thick if the benefit is to be realized. This is many times the thickness of

[35] Cons. Engr., Vancouver, B. C., Canada.

the capillary film, even for asphalt, and, as a consequence, the film would exert hydrostatic pressure equal to its full height (even when it appears to be brittle, asphalt is a highly viscous liquid). This would act to transfer the proportional part of the load when the reservoir was full; but when the reservoir was empty, it would press the up-stream lamina in a radially up-stream direction with a greater tangential tension as a result than the material could stand, unless it were heavily reinforced for the special purpose.

The second method, by a physical separation, using water as a medium to transfer the load, would work when the reservoir was full; but when the reservoir was empty, the space between the laminæ must be emptied also, and this means manual or automatic control. In either case, such factors as silt, débris, ice, and deliberate human intervention—which is by no means impossible—offer too many possibilities of trouble to make the idea comfortable. The thought of deliberate human intervention may seem like borrowing trouble, but it must be remembered that the "cranks" and anarchists are not all dead by any means. It is not long since that one of them tried to wreck the Welland Canal for apparently no good reason, while, during the World War, enemy sympathizers on more than one occasion undertook the deliberate destruction of bridges and other works in Canada.

In one respect, the paper is to be commended. Mr. Noetzli seems to have avoided successfully the idea of wasting acres of paper on the vain attempt to divide the load between the arch and cantilever elements to nine places of decimals. This extreme exactness has always appealed to the writer as an attempt to split a mathematical hair, with the purpose of adding the weight of the left half to that of some saw-log the weight of which has to be guessed anyway.

FREDRIK VOGT,[36] ASSOC. M. AM. SOC. C. E. (by letter).—This interesting paper describes three different features in the design of arch dams, *viz.*, the forked abutments, the overhanging type of "constant-angle arch dam," and the laminated arch elements.

The construction of numerous dams, for instance, Salmon Creek Dam designed by L. R. Jorgensen, M. Am. Soc. C. E., the Kerckhoff Dam designed by B. F. Jakobsen, M. Am. Soc. C. E., and the Gibson and the Deadwood Dams designed by the U. S. Bureau of Reclamation, has proved that single-span arch dams can be used where the sites are about as favorable or less favorable than those shown in Figs. 5 and 7, and without using high gravity wings. When the arches can be founded directly on the rock without high wings or buttresses, this solution seems to offer many advantages. In some cases, however, the topography of the site may invite the use of forked abutments. The Stewart Mountain Dam, of the Salt River Water Users' Association, is an example of forked buttress and gravity wings. In the analysis of such dams it should not be forgotten that the tangential compression of the buttress will increase the span of the arch and thus will increase the rib-shortening pull and the bending stresses.

[36] Docent, Norges Tekniske Höiskole, Trondhjem, Norway.

There is no doubt that the thrust in the arches is inclined at the abutments as assumed by the author, particularly at sites that require a large ratio of span to height. The writer has previously discussed this matter,[37] and the theoretical analysis given at that time was later checked by model tests. Owing to this inclination low buttresses, one-eighth to one-fifth of the height of the dam, will not receive much load if used at sites as shown in Figs. 5 and 7. It is a question whether gravity wings should not be limited to such heights, where possible. For instance, in the case of Dam No. 1 shown in Fig. 5, arch elements with the same radius as that used in the design, but with greater central angles, could be used for greater spans, and thus the arch elements could be founded directly on the rock for 75 to 80% of the total height of the dam instead of only 53% as noted in the design, thus reducing the wings considerably. Such a change will give a smaller rib-shortening pull and smaller stresses in the arch elements; it will give practically the same stiffness against deflection[38] and also practically the same cantilever stresses. In other words, the efficiency of the arch elements will be improved in some respects and, in others, will be virtually unchanged.

However, this possibility of increasing the span of the arch and thus reducing the wings without increasing the radius is due to the fact that rather small central angles of about 90°, have been used at the crest for both Dams Nos. 1 and 2.

As shown by Mr. Jorgensen,[39] it is preferable to use central angles of about 120°, assuming that the cylinder formula is valid. If analyzed by the now generally accepted elastic theory, including also temperature changes, central angles of 150 to 160° are found to give the minimum of concrete, and, therefore, should be preferred where it is possible to obtain good abutments with such large angles.

In the designs of Dams Nos. 1 and 2 the central angles applied at the base of the buttresses are about 130° and 120°, respectively; that is, they are about as suggested by Mr. Jorgensen. Higher up the span of the arch is unchanged, and it is difficult, therefore, to find any reason for the increase of the radius of the arches and the accompanying reduction to 90° at the crest in the central angles. The latter only reduces the efficiency of the arch elements. The writer has emphasized[40] the fact that this use of a variable radius is in disagreement with the constant-angle arch principle and is a disadvantage. If the intention is merely to obtain overhanging arches, this result could easily be secured by the use of a constant radius and a constant angle for the height of the buttresses. For both designs the direction of the buttresses permits central angles as large as 130 degrees.

The first "constant-angle arch dams" were constructed without appreciable over-hang, but where larger angles can be obtained by this means, an overhang seems to be well justified. Previous to the Railroad Canyon Dam referred to by the author, such overhanging dams had been constructed in Italy

[37] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1272.

[38] That is, practically the same coefficient, $\lambda$, in the deflection formula, as shown in *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 564, and Fig. 46, p. 565.

[40] *Engineering News-Record*, 1928, p. 707.

(Chiusella Dam, 158 ft. high, completed in 1925[41]); and in Mexico (Calles Dam, 208 ft. high, completed in 1928[42]). If such over-hang is not to result in vertical tension in the cantilevers, pressure grouting must be applied in the radial contraction joints.

The Dordogne River Dam, in France, referred to by the author in Fig. 9, typifies the spirit of many French engineers. The stresses in the Dordogne River Dam are as much as 800 lb. per sq. in., due to water load only, to which must be added the stresses due to the shrinkage and temperature changes. In this connection reference should be made also to the Selune and Belle Isle en Terre Dams, in France. In all the modern arch dams in France[43] the thickness of the arches is reduced to the limit—for the two last-mentioned dams to 7 and 7½ in. at 50 and 54 ft. head of water—by using very short spans (about 16 ft.) between the buttresses. The experience with dams in the United States, and in Scandinavia, seems to show that this scrimping in thickness, down to the theoretical limit, is not advisable, at least not in cold climates.

In any case, the system applied in the Dordogne River Dam is clear in its action, and the maximum stresses can never be very much greater than the cylinder stresses. However, the safety of such dams is controlled either by automatic valves, or by hand operations of the dam keeper. If the basins between the arches are not filled as water in the main reservoir is rising (for instance, because the valve openings are clogged by ice), or if for any reason they are emptied before the main reservoir is emptied (for example, by a great leakage or a bursted valve or pipe), the maximum stresses can become more than 4 000 lb. per sq. in., and the dam is in danger of collapsing. Furthermore, if the reservoir is emptied and the basins are not, the dam will fail. The writer has seen an earth dam which failed because it was dependent on a spillway with an automatically moving gate and because the dam keeper did not maintain that gate in good working order during the cold season. After observing such field practices, he is suspicious of types of dams which depend for safety on factors that may not be proof aginst erroneous operation. Dams ought to be constructed with higher safety factors than most other structures.

The site of the Dordogne River Dam would be excellent for a single-span arch dam, with a span at the crest only 1.8 to 1.9 times the height, which is less than for two-thirds that of American dams higher than 100 ft. The construction cost of a structure of the accepted type scattered over a wide area and with greatly increased excavation and form work, will probably be considerably more than for a single-span arch dam, even if the latter should demand more concrete when designed for the same stresses.

Compared with the French dam, the lamination suggested by the author has the advantage that the action is independent of automatic devices. On the other hand the static action is not so clear. The author states:

"Assume an elementary horizontal arch with two arch laminæ at a depth of 200 ft. below the crest of a dam. The water pressure at this depth is $62.5 \times 200 = 12\,500$ lb. per sq. ft. The up-stream lamina is assumed to carry one-half this pressure, the other half (6 250 lb. per sq. ft.) being transmitted

[41] *Transactions*, First World Power Conference, Lond., 1924, Vol. II, p. 591.
[42] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1310.
[43] No more than these three are known.

across the joint to the down-stream lamina. Assuming a coefficient of friction in the asphalted joint of 0.5, the frictional resistance in the joint, therefore, would be $0.5 \times 6\,250 = 3\,125$ lb. per sq. ft. (22 lb. per sq. in.). This is rather small as compared to the difference in stress in the concrete on opposite sides of the joint, which may be as much as 200 to 300 lb. per sq. in. It is evident, therefore, that the friction in the asphalted joint between the arch laminæ is not likely to restrain them sufficiently to alter the stresses materially from those indicated by theory."

It should be remembered that the frictional forces involved must be added from the crown section to the abutment, and that, therefore, the total frictional force on each half of the arch will be 50% of the water load on the same half transmitted to the lower lamina if the coefficient of friction is 0.5. If frictional forces 0.5 times the water load are acting in the joint between the two laminæ in the arch shown in Fig. 8 for which the stresses are given in Table 2, the writer has computed additional stresses at some places as great as 680 lb. per sq. in. for that arch according to the elastic theory. This added to the stresses given in Table 2 would increase the maximum total stresses by 110%, which is far beyond all reasonable limits.

However, the actual result will not be so bad since the friction will redistribute the division of the water load on the two laminæ, and the laminated arch, therefore, will not be stressed more than the assumed homogeneous solid arch, but will act about the same.

Another and better way to get an estimate of the importance of the friction in the joints is to investigate the stresses at the assumed joints as they would be if the arch element was made solid. If the shear stresses in the solid arch, acting along the surface where the joint would be, are smaller than the radial compression acting normal to the same surface, multiplied by the coefficient of friction, no sliding can be expected, and the laminated arch will act as a solid arch. Mr. Jakobsen has analyzed such stresses in thick arches.[44] With the simplifications which can be used for slender arches the writer has computed these stresses for the arch element shown in Fig. 8, and finds at the surface of the suggested joint the stresses due to the water load, as follows:

Shear Stresses:

At the crown section,

$$\tau = 0$$

at the abutment section,

$$\tau = 0.0411\,\sigma_0$$

the average for the total length,

$$\tau = 0.0228\,\sigma_0$$

Radial Stresses Normal to the Surface:

At the crown section,

$$\sigma_r = 0.0452\,\sigma_0$$

at the abutment section,

$$\sigma_r = 0.0753\,\sigma_0$$

the average for the total length,

$$\sigma_r = 0.0533\,\sigma_0$$

[44] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 503; see, particularly, Fig. 17, p. 505.

in which, the values of $\sigma_0$ are the stresses according to the cylinder formula. With a coefficient, $f = \frac{\tau}{\sigma_r}$, the friction will prevent all movements and will make the arch act as a solid one. In this way the limit of the coefficient of friction is found to be 0.00 at the crown section, $\frac{0.0411}{0.0753} = 0.545$ at the abutment section, and an average for the total length of $\frac{0.0228}{0.0533} = 0.427$.

For very thick arches this limit approaches unity; for instance, for $t = 0.5r$ and $2\phi_1 = 90°$, the limit is 1.0 at the abutment and about 0.6 as an average.

If the actual coefficient of friction is greater than these limits, the arch will act as if it were solid. If it is smaller, some sliding will be started. However, a sliding will reduce the shear stresses considerably without changing the radial stresses very much. The sliding, therefore, will stop as soon as the shear stresses are reduced to equivalence with the frictional forces. In Table 2 the author has found that for this particular arch the lamination creates a 19% reduction in stresses if there is no friction. With a coefficient of friction of 0.5, used by the author, the actual stress reduction is obviously zero, or nearly so. If a coefficient of friction equal to 0.2 could be obtained, a stress reduction of about 10% could probably be depended on, since the average limit corresponding to no reduction is 0.43.

In comparing the stresses it should also be remembered that the yielding of the foundation reduces the maximum compression in the arch, and that the percentage reduction is greater for thick arches than for thinner or for laminated ones.[45] This correction is not included in Table 2, which, therefore, is not quite fair for the solid arch.

Asphalt can be obtained in a number of grades by admixing with oil; all these grades are liquid if warmed, stiffer if cooled, and brittle and hard if sufficiently cold. Fig. 15 shows how asphalt used as a seal in a water-stop of a dam, has been acting as a liquid. The square opening for the asphalt seal was placed too close to the face of the dam, and the pressure from the semi-liquid asphalt broke the corner between the seal and the face. The writer was informed that this happened because of the summer heat and not by reason of artificial heating. The pressure was developed too fast to be released by slow leakages. This does not mean that the same asphalt could not run through narrow openings. At another joint the writer saw asphalt which had flowed 40 ft. from the up-stream face, through a contraction joint with an 0.03-in. opening at the down-stream face. For a part of the way it may have followed the grouting pipes, but the openings to and from these pipes are generally not wider than the opening of the joint, and at the down-stream face the asphalt was coming out of the joint and not through the pipes (see Fig. 16). The same asphalt was brittle and hard in winter.

[45] Compare the writer's discussion on "Stresses in Thick Arches of Dams," *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 554, particularly Tables 11 and 12. Later, the basic formula is checked by the Stevenson Creek Test Dam results, see *Proceedings*, Am. Soc. C. E., Pt. 3, May, 1928, pp. 124–129.

FIG. 15.—BLOWOUT DUE TO STATIC PRESSURE FROM SEMI-LIQUID ASPHALT.

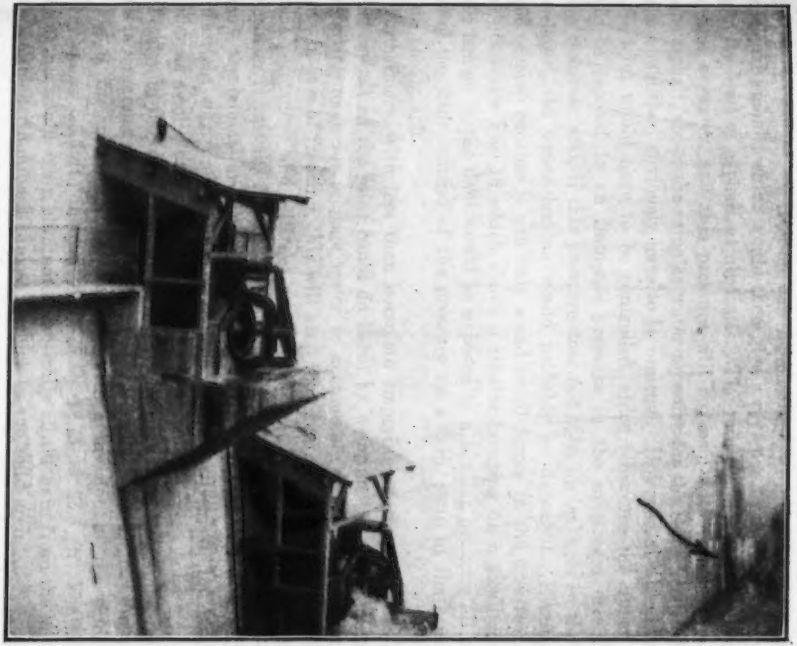

FIG. 16.—ARROW SHOWS PLACE AT WHICH ASPHALT WAS LEAKING OUT AT DOWN-STREAM FACE FROM WATER-STOP AT UP-STREAM FACE AND THROUGH NARROW CONTRACTION JOINT.

A low coefficient of friction can be obtained by using a thick layer of semi-liquid asphalt, which would then give a pressure in the joint corresponding to the head of asphalt at all times. The unit weight of asphalt is about the same as water, and this pressure will be, even with rather slow-flowing plastic asphalt, about the same as water pressure for the same head. All open drains would then obviously have to be omitted. However, the head of liquid in the joint would have to be controlled, since otherwise the upper lamina would be exposed to an immense pressure in the up-stream direction for empty reservoir, and, if this pressure does not open up leakages so that it can be released, the upper lamina would probably be damaged. Eventually, it would collapse because it can only stand small forces in the up-stream direction. Consider Fig. 15 which shows a similar bursting on a small scale; the upper lamina in the dam would be exposed to a similar pressure all over the area of the joint instead of the pressure on a 5-in. strip at the asphalt-seal in the photograph.

Furthermore, with less than complete emptying of the reservoir a semi-liquid asphalt in the joint could do harm by wedging the two laminæ apart, thus giving room for seepage water to accumulate in the upper part of the joint. In case of freezing, this will keep the opening at the crest of the lower lamina permanent and will act as a permanent ice wedge also in case the water later is raised. In this way great extra forces can be introduced both because the laminæ are wedged apart and, therefore, cannot divide the load in the right way, and because a freezing action will make the laminæ act together as a solid arch.

Besides, in the ideal case, the use of a semi-liquid asphalt would divide the loads in a manner similar to that for the Dordogne River Dam. For the arch in Fig. 8, for instance, this would require a division of the thickness in $20.4 + 5.1 = 25.5$ ft., instead of $12.75 + 12.75 = 25.5$ ft. For that arch element this would again eliminate practically all the gain from the lamination since the thicker lamina is almost as thick as the solid arch.

The author does not seem to plan on the use of any liquid or semi-liquid asphalt, and this discussion is only inserted to show that, if one tries to obtain a low coefficient of friction in that way, it is better to adopt a system of controlled filling with water as was done with the Dordogne River Dam.

The question then is whether coefficients of friction less than 0.5, for instance, as assumed by the author, can be obtained for the asphalted joint during the winter, when a grade of asphalt is chosen which is not liquid or semi-liquid enough to produce static pressure in the summer. The writer does not believe that can be expected; the fact is that such grades of asphalt will be almost as hard as stone in the winter. With surfaces made smooth by using steel forms, coefficients of about 0.5, and perhaps as high as 0.7, are probable. The lamination will then be of little or no use for equalizing the arch stresses. With coefficients as low as 0.1 to 0.2, the lamination will be of some use even if it will not reduce the stresses as much as the author has assumed, unless the coefficient of friction is zero.

The author has computed the relative movements at the joint, using a modulus of elasticity of 3 000 000 lb. per sq. in. According to the tests made

by Raymond E. Davis,[46] M. Am. Soc. C. E., it does not seem fair to assume more than 1 500 000 lb. per sq. in. in case of long-time loadings, which will double the relative movements. If the friction is zero, the vertical sliding at some places will usually be several times as great as the horizontal sliding. Friction against this will reduce the effect of the lamination on the cantilever stresses in the same manner as it reduces the effect on the arch stresses.

The lamination of the arch will make this less homogeneous than before. The asphalted joint will act as a water-stop in the middle of the dam, the effect of which will extend all over the structure and, in all probability, it will keep the upper lamina wet from seepage water and the lower lamina dry, since the seepage water is stopped at the joint and drained off there. This at first will produce a considerable shrinkage in the lower lamina and little or no shrinkage in the upper lamina. Secondly, it will give a "sustained modulus of elasticity" for continuous load on the dry lower lamina, which is only about one-half that for the wet upper lamina.[47] The difference in modulus of elasticity in the ratio of 1:2 will change the division of load from 50 + 50% to 33 + 67%, and thus will give additional stresses of 33% for the upper lamina. The difference in shrinkage will exaggerate this condition considerably; a difference of 0.02%, for instance, will introduce another 150 lb. per sq. in., equal to 25% additional stress if based on 600 lb. per sq. in.

It is true that there will be some effects of this kind also in solid arches, but without any doubt the use of a water-tight membrane in the middle of the dam, dividing this into an upper wet and a lower dry part, will increase the non-homogeneity, and thus will increase such additional stresses materially. In a solid arch the water-soaking will be rather uniformly distributed due to capillarity and water pressure; only at the down-stream face will the concrete be dry.

If there is no friction in the joints, the cantilever elements would become comparatively ineffectual, as stated by the author, and the cantilever stresses would be reduced. However, it should be remembered that this is not always desirable. For instance, for the Gibson Dam,[48] the arch stresses would no doubt be much too high if the cantilever action were made ineffectual, and this, therefore, would demand a heavier arch section.

*Conclusion.*—The foregoing discussion leads directly to five conclusions, as follows:

(1) With a coefficient of friction of 0.5, as assumed by the author, the friction will eliminate the benefit of the lamination either entirely or to a very great extent.

(2) The friction can be reduced by using liquid or semi-liquid asphalt grades, but if a liquid is used in the joints, even if it is rather viscous, the filling must be controlled, and then the Dordogne River Dam with water between the arches would prove to be a better pattern.

[48] Constructed by U. S. Bureau of Reclamation, Div. of Load, see *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1295.

(3) The asphalted joint will make the concrete non-homogeneous (different moisture content in the laminæ), and this will introduce additional stresses which are much greater than the reduction which could be obtained by lamination in the case of no friction.

(4) The writer believes that, in most cases, it is desirable either to avoid gravity wings and buttresses or to reduce their height by using a longer span for the arch than is shown in Figs. 5 and 7. The most favorable height of gravity wings can only be found, of course, by comparative designs.

(5) The use of over-hang of the crown cantilever is believed to be a great advantage where the constant-angle arch principle can be better accomplished in that way.

PAUL BAUMAN,[49] M. AM. SOC. C. E. (by letter).—The author has endeavored to eliminate complexities in the interior stability of thick concrete arches by designing laminations to furnish a simple substitute for the cumbersome trial-load method. Unfortunately, his new type which, in principle, is a "telescoped" Dordogne Dam, involves serious physical uncertainties which might readily impair the safety of the structure.

The assumption, for example, that the flexibility of the compound structure is governed by that of the individual rings is hardly justifiable as long as the faces of the rings are in contact. The relative motion of molecules (relative lengthening and shortening) at contact points would add to the restraining influence of sliding friction so as to render the effective frictional coefficient very uncertain.

Furthermore, this coefficient is not a constant for one and the same point; it is a maximum at the time that movement begins (end of rest), and diminishes as movement continues. This feature would tend to cause slips between the laminæ, resulting in "dam quakes", just as it produces slips between geological strata resulting in earthquakes. The ensuing vibrations would not be desirable, to say the least.

On the other hand, it cannot be denied that the lamination would enhance the flexibility of the compound structure and, therefore, would tend to reduce the eccentricity of the line of pressure. As the load on a dam, under normal conditions, is gradually increasing during the initial filling of the reservoir, the up-stream ring would be engaged first; then the next ring would be engaged, etc.

If the spacing between the down-stream face of the up-stream ring and the up-stream face of the one adjacent to it were such as to cause uniform contact as soon as the up-stream ring has its share of the full load on the dam, its elastic behavior, up to this point, would undoubtedly be independent of the remainder of the laminæ. Based on the same premises, a further increase of the load would then engage the first plus the second ring, then the first plus the second plus the third, etc. The $n$th lamina would then be engaged for a load equal to $\frac{n-1}{n}$ times the total load. As soon as contact takes place between

[49] Chf. Designer, Quinton, Code & Hill—Leeds & Barnard, Engrs., Consolidated, Los Angeles, Calif.

two faces, relative motion could undoubtedly still develop, but, even if such motion were disregarded, it is evident that the eccentricity of the line of pressure—and, consequently, the extreme fiber stresses of $n$ combined laminæ—would be materially smaller than that of a monolithic dam of equal cross-section. The structural difficulties involved in such a spacing of faces to provide for deflection would be very serious indeed.

The elastic behavior of a laminated arch is dependent upon the load. The greater the load the smaller is its flexibility. This is a distinguishing characteristic.

The flexibility of an arch slice is described through its ellipse of elasticity or, in other words, through the moments of inertia of its elastic weights about the principal axes of gravity. The fundamental problem in the design of a laminated arch, therefore, is the determination of the effective moment of inertia of its elastic weights which is limited by the elastic behavior of the most flexible, up-stream lamina as a maximum and the elastic behavior of the solid arch with a thickness equal to $n$ laminæ as a minimum.

Assuming for the moment a symmetrical layout and numbering the laminæ consecutively, beginning at the up-stream face, the elastic center, elastic weights, and moments of inertia of Arches 1, 1 + 2, 1 + 2 + 3, etc., are determined.

Their centers of gravity are readily found, the principal axes are located, and the moments of inertia about these axes are determined. The effective moment of inertia of the combined laminæ is $\frac{1}{n}$ times the sum of the moments of inertia of the individual groups (1, 1 + 2, 1 + 2 + 3, etc.), because each of the $n$ combinations contributes $\frac{1}{n}$ parts of its flexibility to the elastic behavior of the entire section.

In Fig. 17 this hypothesis is illustrated for a symmetrical section with three laminæ of equal thickness. It shows clearly the diminishing of the ellipse of elasticity; that is, the decrease of flexibility as the number of laminæ engaged to carry the load increases. (Arches 1, 1 + 2, and 1 + 2 + 3 are designated $A$, $B$, and $C$, respectively, in Fig. 17.)

The elastic weights, $W$, of Arches $A$, $B$, and $C$, are:

$$W_A = \frac{24\left(R_u - \frac{t}{2}\right)\phi_0}{E\,t^3} \qquad (13)$$

$$W_B = \frac{3\,(R_u - t)\,\phi_0}{E\,t^3} \qquad (14)$$

and,

$$W_C = \frac{8\left(R_u - \frac{3\,t}{2}\right)\phi_0}{9\,E\,t^3} \qquad (15)$$

The distances, $y_s'''$, of the elastic centers from the common center of curvature, $C$, are:

$$y_A = \frac{\left(R_u - \frac{t}{2}\right) \sin \phi_0}{\phi_0} \quad \ldots\ldots (16)$$

$$y_B = \frac{(R_u - t) \sin \phi_0}{\phi_0} \quad \ldots\ldots (17)$$

and,

$$y_C = \frac{\left(R_u - \frac{3t}{2}\right) \sin \phi_0}{\phi_0} \quad \ldots\ldots (18)$$

The moment of inertia of the elastic weight, $W$ (about the $x$-$x$ axis), was found graphically as $E\,I\,W = 3.33$ (see Fig. 17).

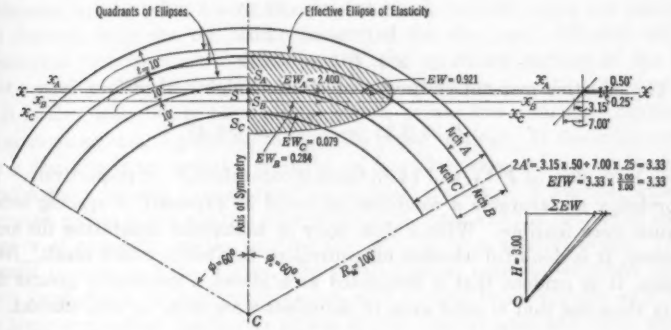

FIG. 17.

The moments of inertia of Arches $A$, $B$, and $C$ (about the $x$-$x$ axis), are (very approximately),[50]

$$I'_A = \frac{24\left(R_u - \frac{t}{2}\right)^3}{E\,t^3} K' \quad \ldots\ldots (19)$$

$$I'_B = \frac{3\,(R_u - t)^3}{E\,t^3} K' \quad \ldots\ldots (20)$$

$$I'_C = \frac{8\left(R_u - \frac{3t}{2}\right)^3}{E\,t^3} K \quad \ldots\ldots (21)$$

in which,

$$K' = \frac{\phi_0}{2} + \frac{\sin 2\,\phi_0}{4} - \frac{\sin^2 \phi_0}{\phi_0}$$

[50] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), top of p. 1675.

About the $y$-$y$ axis, the moments of inertia are:

$$I''_A = \frac{24\left(R_u - \frac{t}{2}\right)^3}{E\,t^3} K'' \quad \ldots\ldots (22)$$

$$I''_B = \frac{3\,(R_u - t)^3}{E\,t^3} K'' \quad \ldots\ldots (23)$$

and,

$$I''_C = \frac{8\left(R_u - \frac{3\,t}{2}\right)}{9\,E\,t^3} K'' \quad \ldots\ldots (24)$$

in which,

$$K'' = \frac{\phi}{2} - \frac{\sin 2\,\phi_0}{4}$$

Introducing numerical values as shown in Fig. 17 there results:

$$E\,I''_A = 493.00$$
$$E\,I''_B = 52.35$$
$$E\,I''_C = 13.07$$
$$\Sigma\,E\,I'' = 558.42$$

The effective moment of inertia of elastic weights, therefore, is:

$$I' = 3.33 + \frac{558.42}{3} = 189.47$$

which is 38.30% of $I''_A$, and 14.45 times greater than $I''_C$, respectively. This is probably as favorable a condition as could be expected, if spacing between laminæ were feasible. With a thin layer of asphaltum separating the arches, however, it is doubtful whether an equivalent flexibility would result. Nevertheless, it is evident that a laminated arch shows a materially greater flexibility than one that is solid even if the joints were 50%, or less, efficient.

F. W. Hanna,[51] M. Am. Soc. C. E. (by letter).—The paper involves interesting questions in arch dam design: As to the superiority of stress analysis for the thin arch ring; the layout problem for dams in irregular canyons; the use of forked abutments to decrease arch spans; the effect of overhang on the layout and stresses; and the substitution of a series of thin arches for a single thick one.

Designers of arch dams are familiar with the difficulties attending the analysis of thick arch rings near the bottom of high dams. When arch formulas are used, tension appears to be involved, both at the crown and at the abutments; while, as a matter of fact, it is probable that combined arch and beam action exist in a complicated form. Undoubtedly, on account of the shortness of the span and depth of the beam, shear provides the bulk of the required resistance. Even if the arch rings at the base were laminated, it is probable that shear along the canyon bottom and walls would still furnish the principal resistance.

The author proposes to use a cone layout for arch dams, but this involves an intricate manipulation of central angles, radius lengths, and overhang.

[51] Chf. Engr. and Gen. Mgr., East Bay Municipal Utility Dist., Oakland, Calif.

Up-stream conic surfaces of arch dams must consist of sections of the surfaces of parent cones. Such sections are parallelogrammatic, trapezoidal, triangular, parabolic, or hyperbolic in nature and are roughly the same as the possible canyon sections suitable for arch dam sites.

In the case of a parallelogrammatic section, the conical surface will be cylindrical as the cylinder is a cone with its vertex at infinity. Both the central angle and radii from top to bottom of the dam can be kept constant, and difficulty with overhang can be obviated. In the case of a triangular section, the vertex of the cone will be at foundation level, and the central angle can be kept constant from top to bottom of the dam, the radii will decrease uniformly from the top to the bottom of the dam, and difficulty will be experienced with overhang. In the case of a trapezoidal section, the vertex of the cone will be below foundation level, the central angle can be kept constant from top to bottom of the dam, the radii will vary uniformly from a maximum at the top to a minimum at the bottom of the dam, and difficulty will be experienced with overhang. In the parabolic or hyperbolic section, the vertex of the cone will be below foundation level, both the central angle and the radii will decrease from the top to the bottom of the dam, and difficulty will be experienced with overhang. Consequently, the up-stream surface of the dam must generally either be warped or subject to overhang.

It is also desirable to have all the crown points and arch ring centers in the same plane and, if possible, to have the plane vertical. If the cross-section of the dam site is an isosceles triangle, an isosceles trapezoid, an equi-angular parallelogram, or any symmetrical curve with respect to a vertical axis, all the crown points in the neutral axes of the arch rings and the centers of curvatures or of symmetry of the neutral axis will lie in a vertical plane. If the triangle or trapezoid is oblique, the parallelogram non-equi-angular, or the curve symmetrical in horizontal planes with respect to an oblique axis, then the plane containing the crown points of the neutral axes and their centers of gravity or of symmetry will be in an oblique plane. In either case the horizontal arch rings will be symmetrical and symmetrically loaded.

If, however, on account of irregularities in the sides of the canyon walls, the cross-section does not conform to the rectilinear boundary of the triangle, trapezoid, or parallelogram, or to the boundary of a curve symmetrical in horizontal planes with respect to an oblique plane, the various arch rings cannot be made symmetrical with reference to a single vertical or inclined plane. If the distances of the crown points at the neutral axes or their centers of curvature from a vertical or an inclined plane are small, only slight errors will be involved in considering them symmetrical and symmetrically loaded.

As stated by Mr. Noetzli, the use of forked abutments in the design of arch dams will promote general symmetry of the dam and will decrease the span and the radii in the upper section.

The excessive weathering of the canyon walls near the top of most dam sites so increases the width as to make the design of the upper part of a high arch dam either uneconomical or infeasible without the construction of abutments to take the place of the missing canyon walls. In order to meet the walls in wide canyons at suitable angles the arch has to be too flat for economy;

and, if tangential abutments of full height are used, they are sometimes so nearly parallel to the canyon walls as to make them miss the walls entirely or to make their dimensions uneconomical. To overcome this difficulty the designers of arch dams have used the principle of forked abutments, the up-stream fork serving in part as a gravity dam of short length to close the reservoir and also sometimes in part as a buttress to resist arch thrust, and the down-stream fork serving only as a buttress to take the remaining thrust of the arch. Usually the buttresses are designed with outward sloping tops so that the weights when combined with the arch thrusts taken by them at all points from the springing lines outward meet the adjacent horizontal planes or foundations at angles less than the friction angle. Whether the inclined arch action should be considered in the design of these buttresses is somewhat questionable, as the amount carried by them is not easily determined and their extra cost due to embodying this additional factor of safety is usually not too great.

Forked abutments somewhat similar to those suggested by the author have been used with success in the Santeetlah Dam and the Calderwood Dam built by the Aluminum Company of America. The writer used this principle also in the preliminary design of an arch dam for the Pardee Dam site for the East Bay Municipal Utility District, Oakland, Calif.

In the Santeetlah Dam the sloping buttresses of the forked abutments were made radial to the arch section at the springing lines; they were heavy enough to take the radial thrust and to throw the remaining thrust of the arch into direct line with the other forks of the abutments; these, in turn, were designed to take this thrust and, as gravity sections, to close the reservoirs at the ends of the arch. In the Calderwood Dam it was found more convenient and economical to use three forks for the abutments. The first forks consist of gravity sections to close the reservoir, running on a radial line from the springing lines at the left abutment and nearly so at the right abutment; the second forks consist of sloping spray walls running along radial lines from the springing lines, sloping downward at a 0.5 to 1 slope, and designed to take the radial thrust and to act as spray walls; the third forks consist of buttresses extending from the ends of the arch in the line of the remaining thrust and sloping downward away from the arch at a 2 to 1 slope. They are designed to take the normal thrusts at the ends of the arch. In the preliminary design of the arch dam for the Pardee Dam site, the forked abutments were computed so that the gravity sections closed the reservoir by the shortest routes to the canyon walls, and the buttresses were designed to slope downward away from the ends of the arch at a 2.5 to 1 slope and to take the entire thrust of the arch.

The effect of overhang down stream at the crown will be beneficial in the control of the central angles and radii, and in carrying the load to the abutments by inclined arch action. However, it complicates the arch ring analyses. An equally important help can be obtained in the adjustment of the radii and central angles through overhang in an up-stream direction adjacent to the abutments. Abutment overhang, however, inclines the arch rings upward and carries the stresses upward at the abutments. This overhang usually occurs

near the base of the dam, however, where the weight of the superstructure and the shortness of the arches counterbalance the bad effect. Advantages are obtained, however, by a combination of an overhang down stream at the crown near the top and an overhang up stream at the abutments near the base of the dam; but the overhang should never be enough to endanger the gravitational stability of the structure.

The writer is not fully convinced that proper transmission of stresses can be made across the laminations in the laminated type of dam. In the first place, imperfections in construction may be such as to cause the load from any lamination to be improperly transmitted to, and distributed on, the next succeeding lamination down stream. The arch rings under water load deflect down stream at the crown and up stream near the abutments. The deflection of the primary arch under water load down stream at the crown will transmit a certain load to the next succeeding arch at the crown, but not necessarily at the abutments. Consequently, the loads on the secondary arches will have different distributions and the deflections of the secondary arches will not conform accurately to those of the primary arch and to each other. These inequalities in loads and deflections will upset the stress calculations and make them uncertain both in the primary and in the secondary arches.

As a matter of fact, the lack of conformity in load distribution and deflections seems to be a serious defect in the laminated arch type of dam. Further, there is the possibility that cracks will form in the thin laminations of the laminated dam, as shown by the experience in the Stevenson Creek Experimental Dam. Moreover, if there is open space between the laminations due to shrinkage in the concrete and to settling under gravity of the asphaltic filling, undue strain may result in the primary arch. Over-deflection of the primary arch near the top of the dam may cause uplift and cracking through strut action in the secondary arches. On the other hand, if insufficient lubrication exists between the laminations, they will not act as separate arches; as a matter of fact, they cannot act fully independently unless there is a frictionless surface between them.

A. A. EREMIN,[52] ASSOC. M. AM. SOC. C. E. (by letter).—The author has indicated a number of limitations of the present methods used in designing thick arch dams due to the "uncertain assumptions" on which computations of the unit stresses are based. In order to simplify doubtful complicated mathematical manipulations in the design of arch dams the author introduces a new type of laminated arch dam composed of thin arches which are separated from each other by sliding joints or films of water. Since the unit stresses in sections of thin arches are more uniform than in thick arches the error in determining stresses in the laminated arch dams by the methods based on the cylindrical formula will be less.

The idea of subdividing compressed thick arch dams is not new; it was proposed in 1894 by the French engineer, Boulé; in 1912 by the Italian engineer, Rutenberg; and, recently, it was applied to actual practice in the French dam on the Dordogne River as stated by Mr. Noetzli.

[52] Asst. Designing Engr., Bridge Dept., State Highway Comm., Sacramento, Calif.

The horizontal deflections of thick arch dams are generally small and their effect on the primary stresses in an arch is commonly neglected. However, in thin arches, deflections are greater and their influence on the stability of the arch must be considered.

For a circular arch with hinged ends acted upon by a uniform radial pressure Professor S. Timoshenko developed the following expression for critical pressure or the maximum pressure beyond which a structure might buckle:[53]

$$q_{cr} = \frac{E\,I}{R^3}\left(\frac{4\,\pi^2}{4\,\phi_1{}^2} - 1\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

It is evident from this formula that the buckling effect in thin arches is inversely proportional to the ratio, $\frac{R^3}{I}$, or $\frac{R}{t}$. Furthermore, in concrete arch dams with central angles of less than 90°, the buckling of the structure need not be feared.

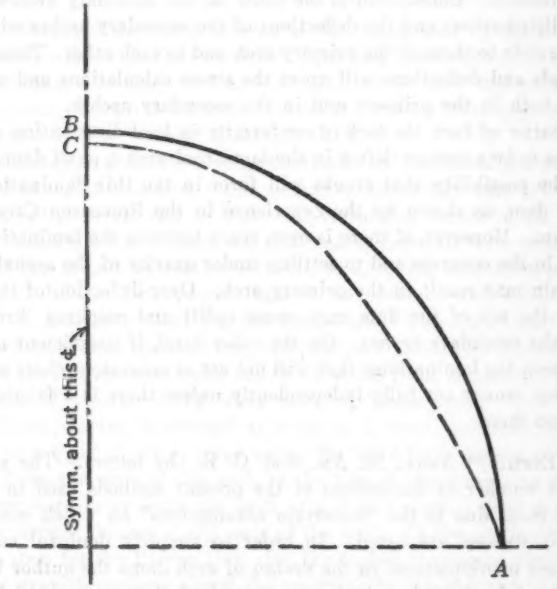

FIG. 18.—RELATIVE DEFLECTION OF AN ARCH DAM SUBJECTED TO A UNIFORM RADIAL PRESSURE.

The author has stated that, neglecting the effect of cantilever action, "the deflections of corresponding points along radial lines will be the same for all arch laminæ." Within practical limits, this statement is correct when it refers to the upper parts of thin arches that are fixed at the bottom. However, near the bottom, deflections vary along the axis of the arch, thus inducing a variation in the distribution of the external pressures carried by arches unless a film of water is provided between laminæ.

[53] "Applied Elasticity," by S. Timoshenko and J. M. Lessels, First Edition, 1925, p. 247.

Professor C. Guidi made an experimental test to determine the deflection of a circular concrete arch, 16 ft. 4¾ in. high, 27 ft. 10½ in. long, and 6¼ in. thick, with a central angle equal to 180 degrees.[54] This arch was fixed at the bottom and both ends, and was subjected to a uniform radial pressure. In Fig. 18 the curve, *AC*, represents the deflection of this arch at Elevation 5 ft. 9 in. Its original unloaded position is represented by the curve, *AB*.

The effect of the variation in deflection of thin arches in the laminated arch dam on primary stresses is probably small. However, it might be rapidly increased with an increase in the number of laminæ used in the dam.

The advantages of using forked abutments have been well indicated by the author. However, when there are certain topographical conditions at a dam site, such that a high, gravity type of wing-wall would be required, the French buttresses with arched flanks, as shown in Fig. 9, would be more suitable.

The arched flanks are more economical than the high, gravity type of wing-walls and the stresses in the buttresses are symmetrically distributed about the center line of the arch. Therefore, the buttresses may be of plain concrete. Steel reinforcement in the main structural members of dams is frequently objectionable because of possible corrosion.

By inclining the center lines of buttresses toward the center line of the main arch in the French type of laminated dam efficient security against sliding is obtained.

The Engineering Profession should appreciate highly the author's development of this theory of designing arch dams and his bold application of the scientific principles to actual practice.

Fred A. Noetzli, M. Am. Soc. C. E. (by letter).—There are several more or less independent features of arch dam form and layout described in this paper, namely, the so-called "forked abutments", a pronounced sloping of the crown of the arch, and the subdivision of the arch, where indicated, into two or more arch laminæ. Furthermore, a simple and convenient method is given whereby the arch stresses at the crown and the abutments, due to uniform water pressure or change of temperature, can be computed from the axial stress (cylinder formula) by mere multiplication with a coefficient to be taken from diagrams given in the paper. Similar diagrams are given for coefficients computed by the theory of "thick" arches.

The three features described in the paper may be used either singly, entirely, or in combinations of two. An arch slightly overhanging in its upper central portion will be found more economical in most cases and will have a better distribution of stresses than an arch dam of the ordinary type.

Forked abutments on one or both sides of the arch will be advantageous at most dam sites. As mentioned by Mr. Hanna, they have been used with success in the Santeetlah and Calderwood (arch) Dams; and the Stewart Mountain (arch) Dam on the Salt River, in Arizona, has forked abutments.

The writer agrees with Mr. Jorgensen that in fairly thin dams the arch should not be laminated. The greatest benefit from laminating is obtained in

[54] *Revue Générale de l'Electricité*, October 29, 1927.

a relatively thick structure. To the extent that they are effective, the laminations tend to give a better stress distribution in the vertical cantilever elements as well as in the horizontal arches. They also improve the distribution of the foundation pressures both under the vertical cantilevers and, laterally, at the arch abutments.

Mr. Jorgensen and Mr. Hanna appear to place considerable reliance on shear resistance for carrying the load in the lower portions of an arch dam. Consideration should be given in this connection to the fact that, at the support of an ordinary cantilever or beam of plain concrete, the shear stresses may be relatively small while the compression or tension stresses from bending may be large enough to produce failure. Small shear values alone, regardless of their magnitude, can not be relied on to insure the stability of a structure, such as a beam, a cantilever, or an arch, unless the tension and compression stresses are also within proper limits.

It is gratifying that, by a different process from the one used by the writer, Professor Cain arrived at the same equation from which the coefficients of Figs. 1 and 2 were computed. A further check is furnished by comparison with Figs. 3 and 4 for "thick" arches. The writer is in full accord with Professor Cain regarding the desirability of vertical radial contraction joints in arch dams. Such vertical joints were purposely omitted in the Stevenson Creek Experimental Arch Dam for the main reason that it was desired to test horizontal arch elements which would be continuous from abutment to abutment so as to permit the measurement of continuous strain curves between abutments without the presence of disturbing irregularities at such joints. Although in the course of the experiment several cracks developed in the dam—particularly a vertical crack in the center extending about 10 ft. from the crest downward and another crack in the same vertical plane extending from the base upward for a distance of about 13 ft.—fortunately none of these crossed the horizontal strain-gauge line at Elevation 30. The continuity of the strain-gauge line at this elevation, therefore, remained unimpaired. The measurement of strains along this line furnished some of the most interesting results of the Test Dam investigation.[55]

There is apparently a misunderstanding regarding the meaning of the term, "rib-shortening" stresses, as used in the derivation of Equations (1) to (5) for the total stresses resulting from the shortening of the arch rib, that is, for direct and bending stresses combined. Professor Cain's Equation (12) gives the direct stresses only.

Mr. Jakobsen and Dr. Vogt present interesting computations relative to the effect of friction in the joints between the arch laminæ. A certain amount of friction will be unavoidable. It is evident, however, that the worst that could happen is that the friction would prevent all movement. The structure then would act simply as a solid arch. However, any movement in a joint would tend to diminish the arch stresses. The extent of this re-adjustment of stresses is in proportion to the tangential movement in the joints. In this connection

[55] Report on Arch Dam Investigation, *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, p. 164.

it is of importance to note that deformations of a laminated arch due to shrinkage and changes of temperature involve very small radial stresses and, consequently, develop very little, if any, friction in the joints. For such deformations, therefore, an adjustment of the stresses could take place approximately as indicated by theory. If water pressure, shrinkage of concrete, and change of temperature of the arch occur in combination with each other, as must usually be assumed for the critical stress conditions, the radial pressure upon the joints remains practically the same as for water pressure alone, while the shear, under certain conditions, may be doubled or tripled, and, accordingly, also the tendency of sliding in the joint.

Mr. Jakobsen recommends the grouting of contraction joints to counteract the shrinkage of the concrete and to improve the stress conditions in arch dams. He states that "this method has been used in connection with a number of dams and apparently with considerable success." The writer has had occasion to get first-hand information on, and, in a few cases, to be directly connected with, such grouting operations on several dams. This experience leads him to believe that the result of grouting of contraction joints in arch dams is very uncertain, to say the least. There is the danger of some portions of the area of a joint being grouted and others not, which results in concentrations of pressures over the grouted areas when the dam is loaded. In the Pacoima (arch) Dam the quantity of cement grout forced through the grout pipes into the contraction joints, under a pressure of 100 lb. per sq. in., was less than that which would have been required for filling the pipes. This indicates that some of the pipes were at least partly clogged by "fines" or other materials during the construction of the dam. Under such conditions it is very doubtful just how much grout was actually forced into the joints themselves and how it was distributed over the section.

The writer agrees with Mr. Werner that it is important to secure monolithic action in the forked abutments. Steel reinforcement placed cross-wise between the buttress and the gravity wing, as indicated in Fig. 7, will promote such monolithic action. Some extra concrete placed in the trough between the buttress and the gravity wing will further improve it. In order to avoid the disadvantages due to shrinkage of the concrete, as pointed out by Mr. Werner, it will be advisable to keep the buttresses as low and as short as possible. As far as the writer knows no difficulty has ever been experienced in arch dams abutting against gravity tangents.

Dr. Vogt refers to theoretical and experimental deductions which indicate that the thrust of the uppermost arches is inclined at the abutments.

Since the crown of the dams shown in the paper is sloping, the actual load-carrying arch elements will be inclined downwardly at the abutments considerably more than in the dams investigated by Dr. Vogt. This is one of the important features of the design as it permits with safety the use of higher forked abutments and consequent shorter radii and spans in the central arch. The most economical layout is best determined by trial. For the uppermost arches it is of advantage to use a relatively long radius and a relatively small central angle so as to direct the arch thrust "into" the hillside rather than

parallel to it, with consequential beneficial results as regards the stability of the forked abutments. For practical reasons these arches are thicker than would be theoretically necessary, and, therefore, the central angles need not be very large to give stresses within permissible limits.

Regarding materials for decreasing friction in the joints between the arch laminæ the writer is emphatically against the use of any substance which—either because of the composition or because of the thickness of the layer—might flow to a considerable extent. He believes that a thin coat of asphaltic paint or some of the other materials mentioned in the paper will be sufficient to enable movement in the joint leading to at least a partial re-adjustment of the arch stresses with consequent beneficial results. The writer is grateful to Dr. Vogt for having emphasized the probability of the up-stream laminæ being stressed relatively more and taking a larger portion of the load than the down-stream laminæ. Dr. Vogt gives as reasons the expansion of the up-stream laminæ due to water-soaking, and a smaller value of a "sustained modulus of elasticity" for continuous load on the dry lower laminæ. In a "thick" arch of a dam the highest stresses occur at the abutment intrados. Along the entire extrados the stresses are relatively small. As an example, consider the arch assumed by Mr. Jakobsen for which $\frac{t}{r} = 0.50$ and $2\phi = 120$ degrees. Assume this arch to be stressed by an axial compression of 250 lb. per sq. in. (cylinder formula). From Figs. 3 and 4, the coefficient, $K$, for the given values of $\frac{t}{r}$ and $2\phi$, was obtained for use in computing the arch stresses. The cylinder stress, multiplied with the values, $K$, gives the stresses in the arch at the crown and abutment directly, as shown in Table 3.

TABLE 3.—Computations for Determining Arch Stress.

| Point of arch. | Axial stress, in pounds per square inch. | $K$. | Arch stress, in pounds per square inch. |
|---|---|---|---|
| Extrados: Crown | 250 | 1.08 | 270 (compression) |
| Extrados: Abutment | 250 | −0.38 | −95 (tension) |
| Intrados: Crown | 250 | 0.12 | 30 (compression) |
| Intrados: Abutment | 250 | 2.52 | 630 (compression) |

Evidently, in the solid arch, the concrete near the extrados is used very inefficiently, the stress being 270 lb. per sq. in. compression at the crown and 95 lb. per sq. in. tension at the abutment, while the greatest stress in the arch is 630 lb. per sq. in. compression at the abutment intrados. Consequently, if subdividing such an arch into two or three laminæ tends to put more load and a correspondingly greater stress on the up-stream arch for the reasons given by Dr. Vogt, the results can be only beneficial. If, in this example, a drop of temperature and shrinkage of concrete were considered, the comparison would be still more strikingly in favor of the laminated type.

If a reliable method of grouting of contraction joints of arch dams were available the writer would recommend that the joints in the up-stream arch be grouted under a higher pressure than those of the down-stream arches. As a result, the up-stream arch would take more stress and, therefore, carry more load than the corresponding parts of the solid arch. Naturally, certain other parts of the arch would be relieved by the same amount of load. Some overstressing of the up-stream arch within reason would be beneficial rather than detrimental to the safety of the structure as a whole, inasmuch as it would lead to a better distribution of the foundation pressures because the thrust of the up-stream arch would engage the up-stream portions of the side abutments which in the solid arch are stressed very little and may even be theoretically under tension. It also should be borne in mind that there is not the remotest possibility of independent failure of the up-stream arch because it could not break through without deflecting and thereby engaging the down-stream arches. This, of course, would relieve the up-stream arch immediately of the assumed excessive load.

Mr. Bauman shows by the ellipse of elasticity the greater degree of flexibility of a laminated arch as compared to that of a solid arch, even if the joints should be only 50% effective. Greater flexibility results in a decrease of the bending stresses due to rib-shortening, temperature drop, and shrinkage, and a corresponding greater efficiency of the arch. Mr. Bauman suggests the possibility of slips between the laminæ. For the arch shown in Fig. 8 a maximum movement of 0.06 in. was computed for a change from no load to full load. It needs a rather vivid imagination to speak of "dam quakes" for such small movements.

Mr. Hanna gives an interesting contribution to the discussion in the description of several arch dams in which some of the characteristics of the type of dam described by the writer have been used to advantage. He also calls attention to the feasibility of an overhang of the arch in an up-stream direction adjacent to the abutments. Mr. Hanna expresses doubt regarding the proper transmission of loads across the lamination joints. In this connection, it is of importance to consider that the second lamina will be cast tightly against the first which previously may have been built one or two lifts higher. Before pouring the second lamina the adjoining face of the first will be painted with asphalt so as to prevent bonding and decrease friction. Nevertheless, the two laminæ will be in direct contact with each other at all points. The effect of shrinkage of the concrete in a transverse direction may tend slightly to open the joint, while on the other hand the overhang of the dam will have the tendency to keep it closed.

Assume the water to rise slowly in the reservoir. It will exert a uniform pressure against the up-stream lamina. In the case of two laminæ in contact with each other both will deflect equally. If the deflection lines of two arches are of practically identical shape (as are the up-stream and the down-stream laminæ of an arch dam), the loads causing these identical deflections must also be practically identical. The water load on the arch, therefore, is divided equally between the two laminæ. If, as assumed by Mr. Hanna, the down-stream arch deflected over a certain distance more than the up-stream arch,

the joint would open naturally. As no load can be transmitted across an open joint the up-stream arch would have to carry the total water load, while the down-stream arch would be without load over this distance. Two or three determinations of arch deflections under these assumptions will quickly convince even the most skeptical that there is no possibility of such conditions arising. Therefore, if the joint does not open, the deflections of the two arches —and also the loads and stresses—must be identical, at least within the limits of similarity between the up-stream and the down-stream arch. The writer, therefore, is unable to agree with Mr. Hanna that "the loads on the secondary arches will have different distributions and the deflections of the secondary arches will not conform accurately to those of the primary arch and to each other."

Mr. Eremin cites Professor Timoshenko's equation for the maximum pressure beyond which an arch might buckle. Thin dams in which $\frac{t}{r}$ is not more than, say, 0.15, require no laminating and in thick dams there will seldom be need of more than one or two joints, so that the question of buckling will scarcely ever arise in this type of structure.

# THE SHANNON POWER DEVELOPMENT IN THE IRISH FREE STATE[1]

By A. R. C. Markl,[2] Jun. Am. Soc. C. E.[3]

With Discussion by Messrs. L. J. Bevan, and A. R. C. Markl.

## Synopsis

This paper aims to present a broad outline of the civil engineering part of the construction of the Shannon Power Development in the Irish Free State. The work was done by German contractors and the construction methods used are representative of the best European practice.

Inasmuch as the manner of dealing with the concrete and rock work did not differ appreciably from American practice under similar circumstances, this part of the description will be restricted to a brief recital of the features peculiar to this particular construction.

The equipment and methods used in building a large waterway, such as the head-race of the power plant, however, present features which are not only fundamentally different from American practice, but which are also without precedent in Europe. With the enormous task of building levees on the Mississippi River looming before American engineers, it is thought that a detailed account of the methods used in excavation and in the building of embankments should prove of particular interest.

## General Description of the Development

Southern Ireland with its 25 000 sq. miles and 3 000 000 inhabitants has very little industry. It uses about 45 000 000 kw-hr. per year; that is, only 15 kw-hr. per person per year as against 650 kw-hr. in the United States. This power is supplied by small local stations at prices ranging as high as 20 cents per kw-hr. When the Irish Free State achieved its independence, the Govern-

[1] Published in April, 1930, *Proceedings*.

[2] Chicago, Ill.

[3] Now Assoc. M. Am. Soc. C E.

ment recognized as one of its foremost tasks the development of the country's latent power resources, with a view to infusing new vigor into its economic life. As early as 1925 the Shannon Electricity Act was passed by the Oireachtas, authorizing the construction of a water power plant on the River Shannon. It is Government-owned, and will supply a minimum of 150 000 000 kw-hr. in 1930, and a maximum of 500 000 000 kw-hr. in a later, more complete, development. The cost of the first part of the work, exclusive of the transmissions and transformer stations, was $16 500 000. Basing estimates on amortization in 40 years and 5.5% interest, and including operating expenses and over-head, the cost per unit at the power house will be 0.80 cent for the first part of the development, and 0.45 cent for the full development. The corresponding cost at the 38-kv. bus-bars at Dublin, Cork, and Limerick, which cities are interconnected by 110-kv. loops, is estimated at a little more than 1 cent per kw-hr.

The conditions for the construction of a large water power plant near Limerick may be considered as favorable. The River Shannon is about 200 miles long, and on its course through the center of the island drains about one-sixth its total area, or 4 000 sq. miles, with a mean annual rainfall of 37 in. The average flow in its lower reaches is 8 500 sec-ft., the highest floods carry 32 500 sec-ft., and the lowest run-off observed was 900 sec-ft.; the ratio of the two latter values is 36 : 1, which compares very favorably with most European rivers. The upper course of the Shannon has very little slope, since the river flows through three extensive lakes, Lough Allen, Lough Ree, and Lough Derg, with a total surface area of more than 100 sq. miles, which serve as natural storage basins. The greatest drop is concentrated between the last-named lake and the tidal estuary of the river, and here it is possible to utilize a head of 100 ft. in a stretch of 17 miles.

## Principal Construction Items

The actual work which had to be undertaken may be subdivided into the following main sections: (1) Raising the banks of the lower lake (Lough Derg) to increase its storage capacity; (2) construction of a diversion dam and canal head-gates; (3) head-race construction; (4) construction of the water-gate, the power station, and ancillary, or secondary, works; and (5) tail-race excavation.

*Storage Capacity Increase.*—Despite their large area, the existing natural lakes were insufficient to provide the storage space required for balancing the water supply between periods of flood and drought. Low embankments had to be thrown up along the sides of the lower lake, and parts of the Upper Shannon had to be regulated. Incidentally, these measures will benefit agriculture by protecting large areas from inundation, and shipping by providing a deeper and straighter navigable channel. This work was done mainly by means of small bucket excavators.

*Diversion Dam and Head-Gates.*—Six miles below Lough Derg (Fig. 1(*a*)), a short distance down stream from a geological fault crossing the Shannon at right angles, a dam which raises the water 25 ft., was built on the crest of the hard red sandstone stratum sloping up against the river at this point.

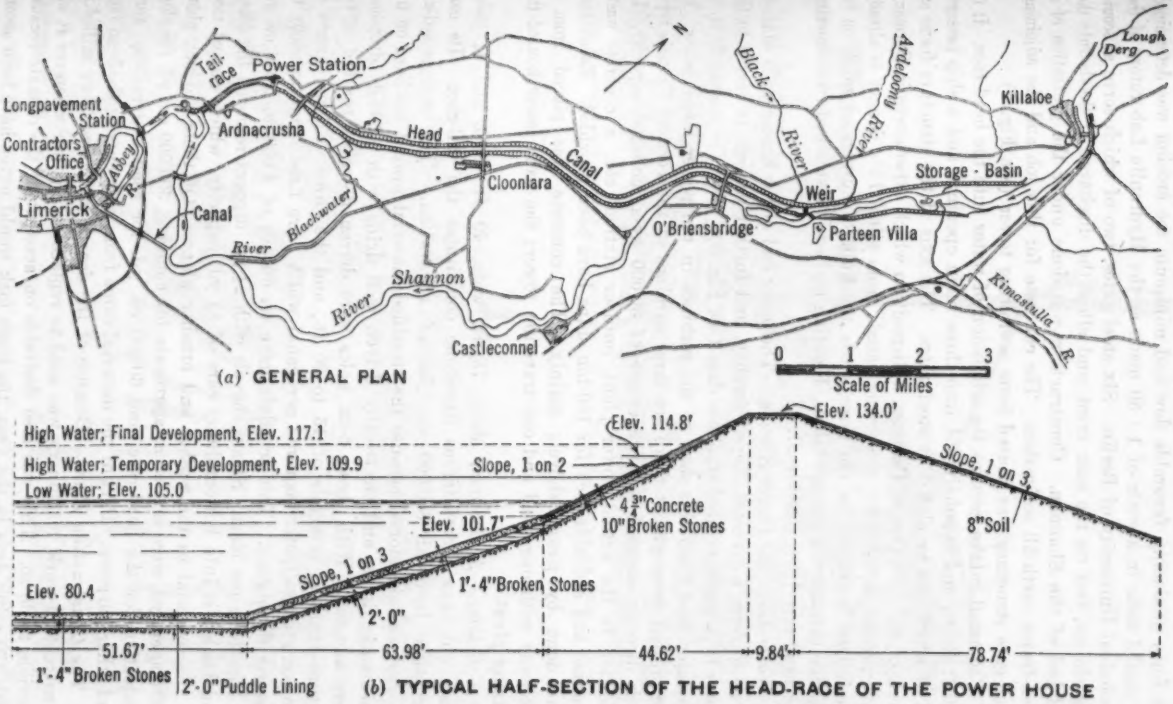

FIG. 1.—PLAN AND SECTION OF THE SHANNON POWER DEVELOPMENT.

This dam is of the ogee overflow type, and has an over-all width of 380 ft.; the form producing favorable flow and minimum toe erosion was determined by model tests in a scale of 1 : 50 made at the Hydraulic Laboratory of the Technical University of Berlin. Six steel gates, two of which serve as scouring sluices, rest on the weir crest, and allow the discharge of floods into the old bed of the Shannon. Construction was done under the protection of a steel-frame earth-fill coffer-dam. The concrete for this job and the adjoining head-gate structure was poured from a chuting tower (see Fig. 2).

The canal intake governs the admission of water into the head-race. It is 320 ft. wide, and is subdivided into three main openings and a ship passage, all of which can be closed by steel gates. The axis of the structure forms an angle of 45° with that of the dam, a disposition which experiences in Germany have proved suitable for protecting canals from silt. This danger is already minimized inasmuch as the river sheds the bulk of suspended solids on its passage through the storage lakes. Floating matter is restrained from entering the head-race by a panel wall.

*Water-Gate and Power Station.*—The lower end of the head-race is widened so as to form a trumpet-shaped forebay, and further passage is barred to the water by a medium-sized concrete dam (see Fig. 3). Short penstocks 20 ft. in diameter lead from this dam to the turbines in the power house below. In the present development there are three turbines of the vertical Francis type, each directly coupled to a generator of 30 000 kv-a. nominal capacity. In addition to the actual power plant, outdoor station, etc., a concrete waste channel and a double lock for 150-ton ships have been provided. Excavation was done by power shovels mainly. The concrete was placed from a cableway with one fixed and one traveling tower; the fixed tower housed the mixing plant.

*Tail-Race.*—A channel, about 75 ft. wide, 40 ft. deep, and 1¼ miles long, cut into carboniferous limestone constitutes the tail-race. Its construction involved 800 000 cu. yd. of excavation. The compressed-air method was abandoned because the stratified material proved too hard on the pneumatic drills, and electrically driven well drills with 1 500-lb. drop-bars were adopted. With these, 8-in. holes were driven down to the bed of the future canal at intervals of 15 to 20 ft., and the three or four charges of ammoniated saltpeter required per canal width were fired simultaneously by electric detonators. This schedule gave an output of 4 000 to 5 000 cu. yd. of limestone per blast. Steam shovels with 2½-yd. dippers removed the débris and loaded it into bottom-dump cars of 8½ yd. capacity, which carried most of the material to the washer and crusher plants. Of their product, about 400 000 cu. yd. were needed as aggregate for concrete, 500 000 cu. yd. for slope protection for the head-race, and 60 000 cu. yd. for road and railway work, and other purposes. Part of the material came from rock cuts in the head-race.

*The Construction Plant.*—Because of the dearth of native labor skilled in construction work, machinery was used to replace man-power wherever it was possible to do so. This was also desirable on account of the climate because, with 270 rainy days in the year, the huge task would never have been accomplished in the scheduled construction period of 3½ years. To this end, 30 000

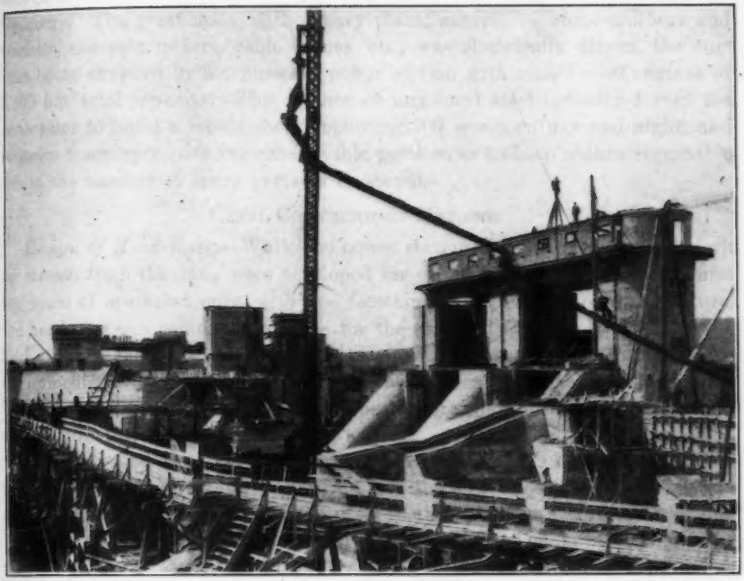

FIG. 2.—POURING CONCRETE FOR DIVERSION DAM. HEAD-GATES TO BE SEEN IN REAR.

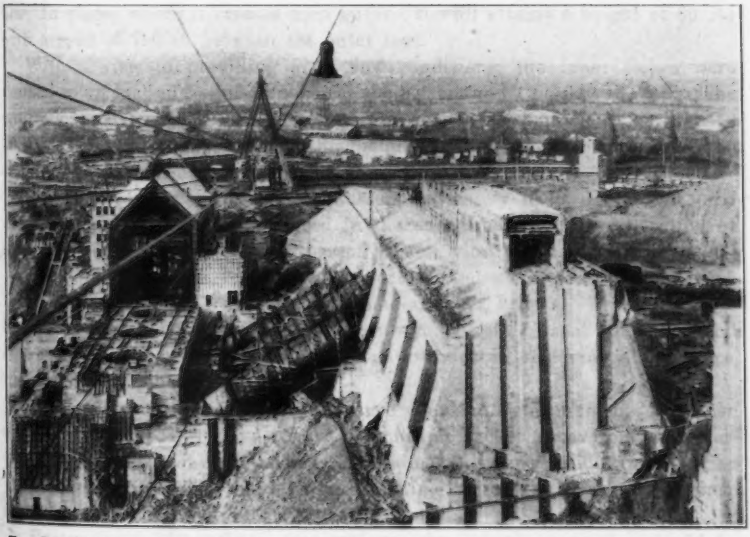

FIG. 3.—SHANNON POWER DEVELOPMENT: TAIL-RACE, POWER STATION, PENSTOCKS, WATER-GATE, FOREBAY OF HEAD-RACE. IN REAR, FIXED TOWER OF CABLEWAY.

tons of construction machinery, large and small, were shipped to Ireland from Germany. The great mass of the heavy plant, excavators, stone-crushers and washers, concrete mixers, cable cranes, etc., was electrically driven, the current being supplied by a temporary power station with nine Diesel engines of 4 500 h.p. total capacity. The absence of any local steel industry forced the contractor to build a repair shop employing 300 workmen day and night, and to order machinery with interchangeable parts so as to keep within reasonable limits the number of spare parts to be stored.

## Canal Construction Methods

*Design of Head-Race.*—While the power station, the tail-race, and all work up stream from the dam, were developed for the anticipated needs of the first ten years of operation only, with due forethought for extension in the future, the head-race was completed at once for the so-called full development, or the final stage of the work. A policy of restricting construction of the head-race to immediate requirements would not have been justifiable economically, inasmuch as present gains would have been more than offset by future excess expenditure for enlarging the waterway.

The head-race, therefore, was built for a capacity of 19 500 sec-ft. Since it was also to serve as a navigation channel, the flow velocity was limited to a maximum of 5 ft. per sec., and the cross-section planned accordingly.

A typical half-section is shown in Fig. 1 (*b*). The head-race has the notable width of 320 ft. between the crowns of the banks, and a depth of as much as 37 ft. in the final development. Only a short length of the canal is entirely in "cut", most of it being constructed partly in cut and partly as fill. In places where it crosses deep gullies, the fill attains a height of 60 ft., with a span of 700 ft. between the outer toes.

With a view to providing good flow conditions, the inner slopes were banked to an inclination of 1 on 3 near the bottom and 1 on 2 at the top. The outer slope of 1 on 3 assured adequate stability for embankments as high as 25 ft. Where the fill exceeded this height, berms were provided, and the slopes were flattened to 1 on 4 and 1 on 5.

Since the total earth excavation was approximately 10 000 000 cu. yd., and similar quantities had to be placed in the enbankments, proper selection of equipment and good disposition thereof became vital problems.

*Preparation of Site.*—The greater part of Ireland is pasture land, each individual plot being fenced in by stone walls or hedges. These obstacles had to be removed first. Walls and tree stumps were blasted out, and small steam shovels on caterpillars did excellent service in removing stone heaps, underbrush, and hedges.

The area to be occupied by the future canal and embankments was then stripped of surface soil by means of multiple-bucket excavators on caterpillars with 35-ft. conveyor booms, and the earth dumped aside for re-soiling the embankment slopes. Usually, two machines worked in series, one of them stripping, and the other rehandling, the material.

*Excavation.*—After these preparations, the actual excavation could be undertaken. The question arose, as to whether to use power shovels or multiple-bucket excavators. Conditions were such that, at first, neither equipment

had any apparent advantage over the other, and only after long and careful study of their respective merits was the decision given in favor of the latter.

To be sure, its ruggedness, mobility, and general usefulness make the power shovel a very valuable tool, especially where excavation is irregular in plan or section and high resistances are encountered; and, therefore, as a matter of course, shovels of various capacities were adopted for foundations and rock work, at the power house and dam sites, as well as in the tail-race.

In the head-race, on the other hand, a shallow trough had to be formed true to design dimensions, and, if possible, in one single operation. The multiple-bucket excavator was found to be the only machine capable of excavating the canal bed and slopes, including breaks in the slopes, without rehandling material or much finishing (see Fig. 4). It raises the excavated material to surface level, and thus eliminates the expensive track work and up-hill haul required in the case of a power shovel operating in the cut, an advantage which is further accentuated where clayey water-bearing soil is encountered. However, it must be conceded that the tenacious marley clay strewn with boulders, which formed the bulk of the excavation on the Shannon work, was no more favorable to the multiple-bucket excavators than to the power shovels. In fact, this material marks the limit of usefulness of this type of excavator; but, even so, with only 30 to 40% of its theoretical capacity, it proved to be the economical superior of the power shovel for this kind of work.

The following are the principal data for one of the excavators used: With a bucket capacity of ½ cu. yd., and 22 to 28 buckets discharged per min., the excavator capacity is 500 cu. yd. per hour theoretically. Under favorable soil conditions, 350 cu. yd. should have been an easy average, but actually no more than 200 cu. yd. were obtained on this job. The length of the bucket ladder is 90 ft., and the maximum depth of excavation is 58 ft. By changing the ladder rigging, the machine can also be made to scrape material down from elevations higher than the track, in which case a height of 46 ft. is the limit. The machine travels at a speed of 16 ft. per min. on the track, that is, in a direction transverse to the bucket chain, and is capable of climbing grades as steep as 2½ per cent. Its service weight is 220 tons.

Portable transformer wagons step the 17 300-volt current supplied by the auxiliary power station down to 3 000, which is the voltage of the main drive, and a transformer inside the excavator steps it down farther to 380 and 220 volts, the tensions at which the advancing drive, the winch drive, and the compressor motor work. The machine requires 150 h.p.

The following were the reasons for adopting electric drive in place of steam for this and other equipment. An electric multiple-bucket excavator uses 0.4 to 0.6 kw-hr. per cu. yd., while a steam-driven machine of the same capacity consumes 3 to 3½ lb. of coal. Considering the necessary haulage in the case of coal, and including the amortization of the auxiliary power plant and transmissions in the price of current, costs per unit excavated and loaded are about balanced; but electric drive has the advantages of higher over-load capacity, instantaneous readiness, and elimination of delays for firing up; it needs no stoker and, therefore, can be operated by one man; and it requires

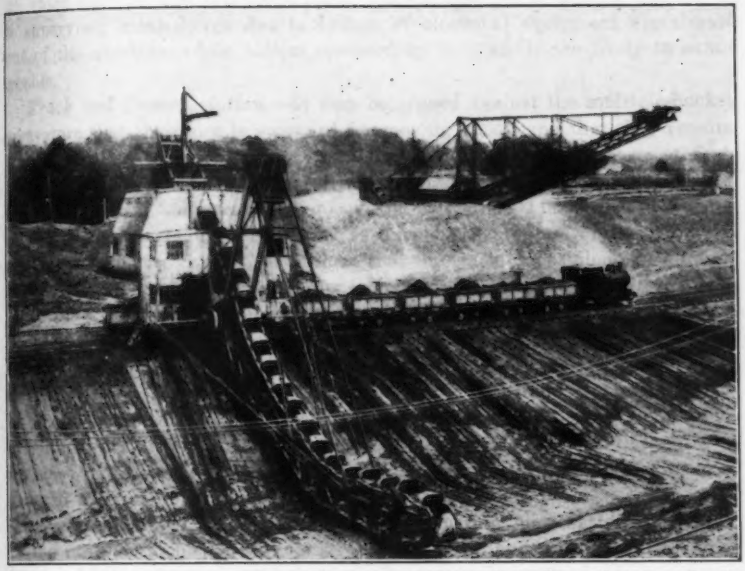

FIG. 4.—VIEW OF MULTIPLE-BUCKET EXCAVATOR FORMING HEAD-RACE, SHANNON POWER DEVELOPMENT. IN REAR, BANK-BUILDING MACHINE.

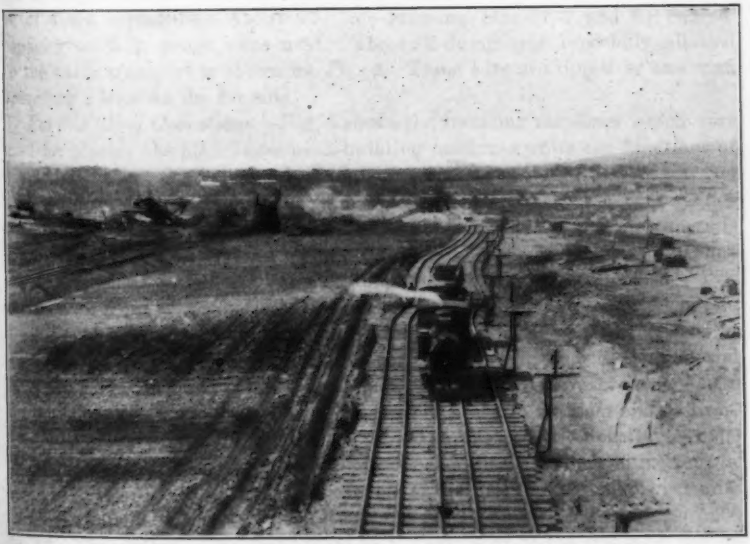

FIG. 5.—SHANNON POWER DEVELOPMENT: TRACK SHIFTER AT WORK.

no water stations and less lubricants. Furthermore, it is cleaner and easier to supervise; break-downs due to failure of electrical equipment are almost out of the question, while boilers operated by field hands are likely to cause trouble.

*Track and Transportation.*—It may be argued against the multiple-bucket excavators that their size is awkward for moving about, and that they require heavy track. Although true, this is not as serious as would appear at first. Transport track is necessary in any case, and this can be laid on top of the 20-ft. ties for the excavator rails. Not more than 1 000 ft. of excavator track are needed per unit, inasmuch as during the progress of the work the rear track units are carried forward, so that the track creeps along in a longitudinal direction. A greater difficulty is presented by the lateral shifting of the track in cases where the excavator chain is not long enough to complete the excavation from one position. Normally, a gang of forty men would be kept busy attending to this work, but with the mechanical track-shifter used no manual labor is required. Fig. 5 shows a track-shifter at work.

The machine consists of a steel truss, 50 ft. long, the ends of which rest on swiveling trucks which ride on the track to be slewed. A jaw at the center of the truss picks up the track at the rails and moves it in a lateral direction, so as to form a kink in the line. Nothing is disconnected, the entire track is moved, including 20-ft. ties and the transmission masts attached thereto. In the next position one kink is straightened out, and a new one produced farther ahead, and so on until the desired position is attained.

Corresponding to the large excavation units used throughout the work and the haulage distance of 1½ miles on the average, the rolling stock also had to be of large capacities. About 900 side-dumping cars of 7 and 8½ cu. yd. capacity on 3-ft. gauge were used. The side-dump type especially allotted to the earth transport is shown on Fig. 4. These cars are tipped by one man operating a lever on the far side.

*Earth-Filling Operations.*—Fig. 6 shows the traveling machines which were used for placing the fill. These bank-building machines unite the functions of a multiple-bucket excavator and a belt conveyer. They weigh 240 tons, travel at a speed of 27 ft. per min., and climb grades as steep as 3⅓ per cent. They run on four rails laid on ties 20 ft. long, which also accommodate the rails for the earth transport trains. The latter dump their material into a trench about 8 ft. deep which the bank-building machine itself has formed. Two chains with ½-cu. yd. buckets pick the material up from this feeder trench, and drop it into a hopper which discharges on to a 36-in. belt running upward at a gradient of 20° with a speed of 300 ft. per min. From this belt, the material falls upon a second belt which travels along a boom and is reversible. These two qualities combine to permit covering a width of 125 ft. from one position. The maximum dumping height is 50 ft. The theoretical capacity is 1 000 cu. yd. per hour, corresponding to twice 25 bucket discharges per min.; that is, there were two bucket ladders, each capable of discharging 25 buckets per min. The actual quantities placed in an average 18-hour day were from 6 000 to 7 500 cu. yd. This output is governed more by the efficiency of the transport system than by the machine's performance, and could be doubled under favorable circumstances.

It has been mentioned before that, to shorten interruptions due to repairs and reduce the required stock of spare parts, units of the different machines were made interchangeable. This idea was applied not only to mechanical parts such as excavator buckets, chain links, etc., but also to the electric equipment. Thus, the bank-building machines were equipped with the same types of motors, as far as feasible, as the multiple-bucket excavators. The two bucket chains and the upper conveyor belt were driven by 50-kw. units each and the lower belt by a 22-kw. motor. Besides these, there were the drives for the two winches for raising and lowering the bucket chains, a drive moving the lower belt along the boom, the advancing drive, and drives for the two pumps which were in readiness to supply water for sprinkling the fill if required.

*Comparison with Other Methods.*—Having described the machinery introduced, it may be well to compare its performance with other methods of constructing embankments. The time-honored method of building up the fill by dumping earth from tracks which are jacked up by a gang of men as the work progresses, was out of the question. The red marl is an excellent material as regards water-tightness, inasmuch as no more seepage than 0.1 gal. per sq. ft. per hour has been observed, but it is rather easily saturated with water, and it then tends to flow and slump together. Under these circumstances the track work, which plays an important part in this method, in any case, would have made the undertaking very expensive; the frequent rains would have stopped the work for days; and progress would have been very slow.

Two reasons mainly argue against the hydraulic-fill method: First, the quantity of water required would have to be carried from the river in a pipe line several miles long; and, second, a reason which in itself was sufficient to make the contractors abandon the idea, the material was wet enough as it was, in fact, part of it had to be excluded on account of its saturation and corresponding lack of stability which would have imperiled the embankments. Moreover, this method requires auxiliary equipment, such as drag-lines for building the shoulders, derricks, flumes, booster pumps, etc., and there would have been extensive auxiliary operations.

Dumping the material from trestles would have been another method; but apart from the great quantities of imported timber required for 15 miles of embankment, and the necessity of raising, not only the earth, but also the dead load of the locomotives and cars, to high elevations, there is the prejudice against leaving trestle bents in the completed fill.

*General Advantages of New Method.*—It is believed that the method adopted combines the advantages of the other systems without suffering from their drawbacks. Of all applicable methods, it is the one which does not require equipment of any description to travel or operate on new fill; the bank-building machine was the only unit used, and it traveled on the firm undisturbed ground at the land side of the embankment.

The two principal requirements for a structure used for impounding water are stability and impermeability. Apart from intelligent design of the cross-section, these requirements can be fulfilled by providing proper distribution of the material according to its water-tightness and weight, proper compacting of the fill, and avoidance of planes of weakness.

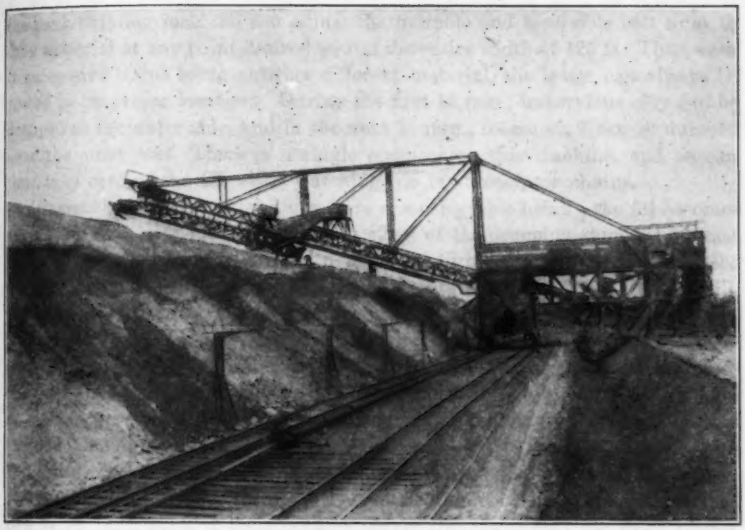

FIG. 6.—VIEW OF BANK-BUILDING MACHINE, SHANNON POWER DEVELOPMENT.

FIG. 7.—PLACING CONCRETE CANAL LINING ON STONE BED, SHANNON POWER DEVELOPMENT.

By pressing a contact button on the switchboard at his side, the operator of the bank-building machine can adjust the movable and reversible belt so as to drop material at any point desired within the entire width of 125 ft. Thus, even if successive trains bring entirely different material, the latter can always be placed in its proper location. During the first 15 min., impervious clay can be dropped at the water side, and in the next 15 min., coarse stuff can be dumped near the outer toe. There is a single operator on this machine, and he can thus take care of the fill while watching his two excavator chains.

Inasmuch as the material drops from a considerable height, the fill becomes very dense and compact. The tamping effect of the dropping stones is at least equivalent to that of a roller, and under some circumstances its effect will be greater. Moreover, there is the absolute certainty that every inch of fill, vertical and horizontal, has been compacted.

Rolled fills have a tendency to show what may be called "pancake" structure. Between well-compacted layers there occur looser strata which offer less obstruction to seepage. In the method described herein horizontal planes do not occur. When the lower conveyor belt is kept in a fixed position and the machine travels parallel to the canal axis, a longitudinal pile of earth is formed. Piles of, say, 5 ft. are built up side by side, and then the valleys are filled and new ridges formed. The whole dam consists of diamond-shaped prisms, so that, even if their contact planes did operate as weakness planes, the percolating water would have to climb one ridge after the other. Actually, the new material has been observed to pierce the old, and thus it forms a good bond. Moreover, the bank-building machines are equipped with sprinkler pipes, so that any desired consistency may be obtained.

## The Finishing Work

Since care was taken to excavate the canal and fill the embankments to the proper level and slope, there was little dressing to be done. For additional safety the water faces received a special layer of clay puddle 1 to 2 ft. thick, which again was protected by rip-rap 12 to 16 in. thick. In the zone where water-level variations and wave action were to be expected, a concrete slab, 4¾ in. thick, was added as a further precaution. The unprotected banks and crown were re-soiled with the humus laid aside for this purpose in the beginning. For part of this work the bank-building machine could again be utilized; but part of it was done with the aid of swivel cranes. The latter also served for placing the rip-rap and concrete. Fig. 7 illustrates these operations.

## Conclusion

A new method for handling large embankment building contracts has been explained. It is especially adapted to construction work involving great longitudinal extension. While it is mainly intended for handling lighter earths, it has also proved economical under severe conditions, in wet and viscous soil, and in a climate unfavorable to outdoor construction work. This fact is illustrated by the low price at which the work could be done; 1 cu. yd. of excavation and fill, including haulage, costs little more than 20 cents.

The work described in this paper was done by the firm of Siemens-Bau Union, as sub-contractors for the Siemens-Schuckert Works, Berlin, Germany.

## DISCUSSION

L. J. BEVAN,[4] M. AM. SOC. C. E. (by letter).—This paper presents in excellent form an interesting description of a brave project. From a power point of view Ireland is in an undeveloped condition similar to that of the United States about 1900. It has a total installation of 27 000 kw., with an urban population of 1 000 000, or 0.027 kw. per inhabitant. The annual consumption of 40 000 000 kw-hr. in 1920 when the Shannon Development was being proposed was 40 kw-hr. per inhabitant, as compared with 71 kw-hr. for all Europe and 472 kw-hr. for the United States. Economically, the Shannon Project should do much for the prosperity of Ireland.

This was referred to as a brave project primarily because of the large amount of power contemplated—500 000 000 kw-hr.—from 37 in. of rainfall on 4 000 sq. miles of drainage area, through a 100-ft. fall. At 80% efficiency from water to bus-bar 530 cu. ft. of water are required per kilowatt-hour. The output contemplated from the first development is 150 000 000 kw-hr., which corresponds to an average annual flow of 2 520 cu. ft. per sec., or a run-off-rainfall ratio of 23 per cent. This is reasonably to be expected.

The ultimate development, 500 000 000 kw-hr., similarly requires an average annual flow of 8 520 sec-ft., or a run-off-rainfall ratio of 77 per cent. Such a run-off ratio is so large that a further elaboration of this phase of the project would be of intense interest.

A. R. C. MARKL,[5] JUN. AM. SOC. C. E. (by letter).—The general description of the development and its basis was curtailed by the writer to a minimum, so as to provide more space for the explanation of a novel method of handling earthwork, which formed the principal object of the paper. Mr. Bevan's questions demand an elaboration which would seem to be beyond its original purpose. Perhaps the following figures may serve as a reply.

In the 4 011-sq. mile area from which the Shannon River draws its water, an average annual rainfall of 37.25 in. obtains, corresponding to a total of 347 436 000 000 cu. ft. per year. Due to a signal lack of forests and the rockiness of the ground, 75 to 78% of this amount, that is, 270 156 000 000 cu. ft. per year, or 8 475 sec-ft., flow off. With a head varying between 93.5 and 110.7 ft., dependent on the tides, which travel up the tail-race, and an estimated rate of 584.8 cu. ft. per kw-hr., this produces 462 000 000 kw-hr. at the bus-bars.

The maximum flow occurs during the winter, while in the months from May to September rarely much more than 3 000 cu. ft. per sec. are carried by the river. This distribution, of course, is fortunate inasmuch as it produces a coincidence of supply and demand. An effective storage capacity of 20 235 000 000 cu. ft., which serves to achieve a complete balance of the water household, is obtained by providing for water-level variations of between 4.4 and 12.0 ft. at the three principal lakes through which the Shannon River flows. These lakes, Loughs Allen, Ree, and Derg, cover a total area of 101 sq. miles.

# PLASTIC FLOW IN CONCRETE ARCHES[1]

By Lorenz G. Straub,[2] Jun. Am. Soc. C. E.

With Discussion by Messrs. B. F. Jakobsen, C. A. P. Turner, Edward Godfrey, J. H. Griffith, Charles W. Comstock, A. A. Eremin, J. Melan, Fredrik Vogt and Herbert J. Gilkey, E. Probst, Paul Bauman, G. C. Staehle, A. Floris, and Lorenz G. Straub.

## Synopsis

Many materials of construction, especially concrete during the first few months after fabrication, do not follow the laws upon which the theory of elasticity in its many forms is based. Yet this theory has been persistently used and elaborated for indeterminate structures, regardless of the material. Such factors as the yield of a stressed body with time, often called "hysteresis", and the variation of the ratio of stress to elastic strain, when at all accounted for in a structural analysis, have generally been analyzed in some more or less unscientific method of guess. For concrete arches, especially in Europe, construction is frequently furthered, that is, by the introduction of temporary hinges, hydraulic jacks, etc., in such a manner that these indeterminate factors can be controlled during the construction and early life of the structure.

Obviously, the ordinary theory of elasticity is entirely inadequate for studying stresses in a statically indeterminate structure made of a material which, when under load, yields with time as well as stress and does not obey Hooke's law for elastic deformation. To fill this need, methods of analysis have been developed by the writer based on experiment. These methods provide a much more general statement of the displacements and deformations

[1] This paper was developed from a phase of an unpublished investigation made by the writer while a "Fellow" in Civil Engineering at the University of Illinois, 1925–27. The title of the manuscript is "Neglected Factors in the Analysis of Stresses in Concrete Arches." Published in January, 1930, *Proceedings*.

[2] Associate Prof. of Hydraulics, Univ. of Minnesota, Minneapolis, Minn.

in structures than is given by the ordinary theory of elasticity because they fit a greater number of properties of materials. Further, they take the exact form of the usual theory of elasticity when plastic deformation is not considered and Hooke's law is assumed to apply. For convenience, the proposed methods of analysis have been termed the "theory of plasticity" and the "proposed theory of elasticity". Although these theories were developed in particular to investigate changes and variations of the stressed condition of concrete arches due to plastic flow, they are of general significance in structural design.

These investigations show definitely that one may be led astray in drawing conclusions regarding the stressed condition of an arch, even if based upon precise and accurate measurements of deformations. The studies indicate that it is even possible to find observed deformations to check the results of analysis by the ordinary elastic theory and yet the resulting conclusions might be wrong. Such misconceptions are readily verified by the procedures herein proposed.

Statements that a locally overstressed point in a structure relieves itself as a result of plastic flow, are shown to be unwarranted and misleading. A much clearer conception is given with regard to shrinkage stresses, temperature stresses, effects resulting from movement of arch abutments, etc. Valuable inferences may be drawn as to the proper interval before removing the arch centering.

## Nomenclature

Ordinarily, the nomenclature for arches is quite involved. When, in addition, such factors as plastic flow and variable stress-strain relations are considered, necessarily it becomes very cumbersome. Hence, some duplication has been used, but it has allowed simplification, and should not lead to confusion. In most instances, $H_0$ has been used to designate the neutral point horizontal thrust due to all causes, that is, superimposed load, dead load, rib-shortening, etc.; in a few cases, it refers to the thrust resulting only from dead and live loads.

As much as practicable of the ordinary American nomenclature for arches has been used. Simplifications, or rather condensations, and additions have also been adopted to make cumbersome algebraic expressions easy to handle. As an example, the symbol, $V$, has been used to replace a frequently recurring algebraic expression, much the same as the ordinary substitution of $I$, for the moment of inertia of a section.

Subscripts denote reference points and causes; for example, $H_{0\text{-}RS}$ indicates the horizontal thrust considered to act through the neutral point, $O$, of an arch, due to rib-shortening under load. Prime marks (superscripts) over a letter denoting a variable distance indicate a definite distance to a particular point or line. Thus, while $z$ indicates the distance from the centroidal axis

of a section to any point in the plane of the section, $z'$ refers to the distance from the centroidal axis of the section to the line of action of the thrust acting upon the section.

In general, distances are considered positive when measured upward or to the right. Similarly, external force components having their sense upward or to the right are positive.

Thrusts acting within a member are considered positive when they cause tension. Shear at a section in a horizontal or inclined member is positive when the section resists impending motion upward at the left portion of the structure. In general, moments in the rib of an arch are called positive when they increase the compression at the extrados and decrease it at the intrados.

Angles are measured positive in a counter-clockwise direction from the initial line.

*Notation.*—The following nomenclature is common to the analyses presented. The less common terms are not included, but will be defined as they are introduced into the discussion.

$d\xi$ = the shortening along the arch axis of a differential length of the rib.

$d\tau$ = the transverse or sliding movement within a differential length.

$d\phi$ = the angle change within a differential length.

$ds$ = a differential length of a structure measured along the centroidal axis.

$\Delta t°$ = the total temperature change, in degrees Fahrenheit.

$\alpha$ = the angle between a tangent to the arch axis and the $x$-axis of co-ordinates.

$\beta$ = the angle which the quasi-horizontal $x$-axis, for an unsymmetrical arch, makes with the horizontal.

$\theta$ = the change in slope of the tangent at a point on a structure.

$\gamma$ = the total unit of shrinkage of a given concrete at a particular time.

$\delta_1, \delta_2, \delta_n$ = respectively, the displacement of points in a structure.

$\delta_{xR}, \delta_{xL}$ = respectively, the permanent displacements of the right and left springings of an arch in the direction of the $x$-axis of co-ordinates.

$\delta_{yR}, \delta_{yL}$ = respectively, the permanent displacements of the right and left springings of an arch in the direction of the $y$-axis of co-ordinates.

$\delta_{rR}, \delta_{rL}$ = respectively, the permanent rotational displacements of the right and left springings of an arch.

$\epsilon$ = the unit elastic deformation.

$\epsilon_z$ = the unit elastic deformation at a distance, $z$, from the centroidal axis.

$\epsilon_u$ = the unit elastic deformation at a distance, $u$, from the center of elastic rotation.

$\epsilon_u'$ = the unit elastic deformation along the centroidal axis.

$\mu$ = the coefficient of expansion per degree Fahrenheit.

$\rho$ = the unit of plastic deformation.

$\rho_v$ = the unit of plastic deformation at a distance, $v$, from the center of plastic rotation.

$\sigma$ = unit stress.

$\sigma_z$ = unit stress at a distance, $z$, from the centroidal axis.

$\sigma_u$ = unit stress at a distance, $u$, from the center of elastic rotation.

$b$ = the width of a section.

$c$ = the distance from the centroidal axis of a section to the outer fiber.

$c_0$ = the distance from the centroidal axis to the outer fiber for a normal section at the crown of an arch.

$d$ = the thickness of a normal section.

$d_0$ = the thickness of an arch at the crown.

$E$ = Young's modulus of elasticity.

$f$ = rise of arch from springing to crown.

$f', f'', f'''$, these terms have been used freely to designate functions and constant factors in terms, especially where only relative values are of importance.

$H_0$ = the reaction at the center of co-ordinates considered to act in line with the $x$-axis at the end of a rigid arm fixed to the arch at the springing.

$H_{0\text{-}DL}$ = the horizontal thrust considered to act through the neutral point due to the dead load, that is, neglecting all effects of rib-shortening, temperature change, or shrinkage.

$H_{0\text{-}RS}$ = the horizontal thrust considered to act through the neutral point as a result of rib-shortening due to the compression of the arch.

$H_R$ = the horizontal reaction in a symmetrical arch, or quasi-horizontal reaction in an unsymmetrical arch, at the right support when the arch is considered as a simple beam.

$I = \frac{2}{3} bc^3$ = the moment of inertia of a normal section according to the ordinary theory of elasticity.

$K$ = a parameter in the exponential equation defining plastic deformation.

$k$ = a parameter in the exponential equation defining elastic deformation.

$l$ = the span of the arch measured parallel to the $x$-axis.

$l'$ = the vertical distance between springings of the arch measured parallel to the $y$-axis.

$\Delta l$ = increment or change in $l$, due to deformation of the arch.

$\Delta l'$ = increment in $l'$, due to deformation.

$\Delta l_{RS}, \Delta l'_{RS}$ = increments, respectively, in $l$ and $l'$ due to rib-shortening in the arch.

$m$ = an exponent of stress determined from experiment and defining the rate of elastic deformation with change in stress. The number, $m$, may also appear in equations as a coefficient.

$M$ = the bending moment.

$M_0$ = the bending moment on a lever arm extending from the springing to the center of co-ordinates.

$M_x$ = the bending moment at a section of the arch having the abscissa, $x$.

$M_d$ = the bending moment caused by statically determinate forces.

$M_i$ = the bending moment caused by statically indeterminate forces.

$M_{d\text{-}LL}, M_{d\text{-}DL}$
$M_{i\text{-}LL}, M_{i\text{-}DL}$ = respectively, the statically determinate moments due to live load and dead load on a structure, and the statically indeterminate moments due to live load and dead load on the structure.

$N$ = the normal component of the resultant thrust acting on a radial section of the arch.

$N_x$, $T_x$, $S_x$ = respectively, the normal thrust, resultant thrust, and shear at a section of the arch having the abscissa, $x$.

$p$ = an exponent of stress determined from experiment and defining the rate of plastic deformation with a change in stress. The number, $p$, may also appear as a coefficient in equations which have been differentiated or integrated.

$q$ = an exponent of time determined from experiment and defining the rate of plastic deformation with duration of loading.

$P_1, P_2, \ldots P_n$ = concentrated loads.

$$Q = \left(b\, c^{\frac{1+2m}{m}} \times \frac{2m}{1+2m}\right).$$

$$S = \left(b\, c^{\frac{1+2p}{p}} \times \frac{2p}{1+2p}\right).$$

$S$ = also, the shear component of the resultant thrust acting on a radial section of the arch.

$s$ = the length of the arch axis.

$T$ = the resultant thrust on a radial section of the arch.

$t$ = the duration of a stressed condition, in days.

$T_{RS}$, $N_{RS}$, $S_{RS}$, and $M_{RS}$ = the resultant thrust, normal thrust, shear, and moment at a section in an arch due to a horizontal rib-shortening thrust, $H_{0\text{-}RS}$.

$$U = b\, c^{\frac{1+m}{m}} \times \frac{m}{1+m}\left[\left(\frac{u'}{c}+1\right)^{\frac{1+m}{m}} - \left(\frac{u'}{c}-1\right)^{\frac{1+m}{m}}\right].$$

$$U' = \frac{m}{1+m}\left[\left(\frac{u'}{c}+1\right)^{\frac{1+m}{m}} - \left(\frac{u'}{c}-1\right)^{\frac{1+m}{m}}\right].$$

$$V = b\, c^{\frac{1+p}{p}} \times \frac{p}{1+p}\left[\left(\frac{v'}{c}+1\right)^{\frac{1+p}{p}} - \left(\frac{v'}{c}-1\right)^{\frac{1+p}{p}}\right].$$

$$V' = \frac{p}{1+p}\left[\left(\frac{v'}{c}+1\right)^{\frac{1+p}{p}} - \left(\frac{v'}{c}-1\right)^{\frac{1+p}{p}}\right].$$

$V_0$ = the vertical reaction at the center of co-ordinates, considered to act at the end of a rigid arm fixed to the arch at the springing.

$u$ = the distance from the center of elastic deformation to a fiber in a section.

$u'$ = the distance from the center of elastic deformation at a section to the centroidal axis.

$v$ = the distance from the center of plastic deformation to a fiber in a section.

$v'$ = the distance from the center of plastic deformation at a section to the centroidal axis.

$V_1, V_2, \ldots V_n$, and $H_1, H_2, \ldots H_n$ = the vertical and horizontal or quasi-horizontal components, respectively, of the forces, $P_1, P_2, \ldots P_n$.

$V_R$, $V_L$ = the vertical reaction at the right and left supports, respectively, of an arch considered as a simple beam.

$w$ = the magnitude of a uniformly distributed load per foot of length. (In a few instances, $w$ is used to designate the distance from the center of combined elastic and plastic deformation to a fiber in a section.)

$x, y$ = respectively, abscissa and ordinate of a point referred to a system of co-ordinates.
$z$ = the distance of a fiber from the centroidal axis.
$z'$ = the eccentricity of the line of thrust with respect to the arch axis.

## I.—GENERAL STATIC AND GEOMETRIC RELATIONS FOR A DEFORMED ARCH

*Fundamental Relations.*—In considering the action of any structure under load, be the structure statically determinate or indeterminate, attention is given to three principal items. These are:

1.—Geometric Relations.—The relation of the angle changes and translations of the differential parts of the structure must be such that the geometric requirements imposed on the structure are fulfilled, for example, constant span length, etc.

2.—Static Equilibrium.—The sum of the components in any direction of all forces acting on the whole structure, or on any part of the structure, must be equal to zero; the sum of the moments acting on the whole, or on any part of, the structure must be equal to zero.

3.—Properties of the Material of Construction.—Deformations and stresses in differential parts of the structure must be so related as to satisfy the properties of the material, for example, the ratio of stress to strain should correspond to that obtained by experiment.

If a structure is statically determinate, the reactions resulting from a given condition of loading can be found without considering the properties of the material. However, even then, the internal stresses due to a given loading are dependent on the elastic properties of the material, and in some cases may involve the plastic properties or deformation with time as well as stress.

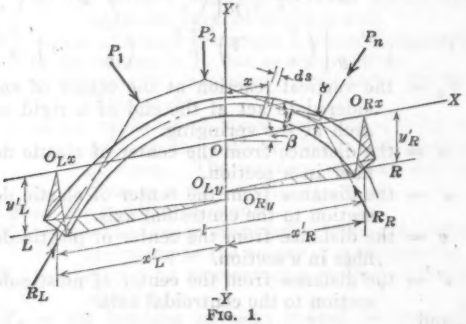

FIG. 1.

When a statically indeterminate structure is analyzed, all three of the aforementioned factors must be combined into equations before a satisfactory solution can be obtained.

*Development of Geometric Relations.*—Consider an arch of arbitrary shape (Fig. 1) subjected to any system of loading in its plane. Due to the assumed loads, $P_1$, $P_2$, $P_n$, there are the reactions, $R_L$ and $R_R$, at the left and right ends, respectively.

After loading (Fig. 2), the arch assumes a new conformation dependent on the movement of the abutments, the bending, and the elongation and shortening of elemental lengths of the arch rib. The deformations may be due to any one or any combination of the following causes:

(1) Rotation or translation of the abutments.
(2) Temperature change.
(3) Shrinkage of materials composing the arch.
(4) Plastic flow of materials composing the arch.
(5) Elastic deformation due to stress.

Assume (Fig. 1) a center of co-ordinates, $O$, and co-ordinate axes, $x$ and $y$. A rigid lever arm is assumed to be connected to each springing and extended to the $x$-axis and parallel to the $y$-axis. The length of the left lever arm is $y'_L$; that at the right is $y'_R$. Similarly, rigid lever arms of lengths, $x'_L$ and $x'_R$, are connected to the left and right springing, respectively, and extended to the $y$-axis and parallel to the $x$-axis.

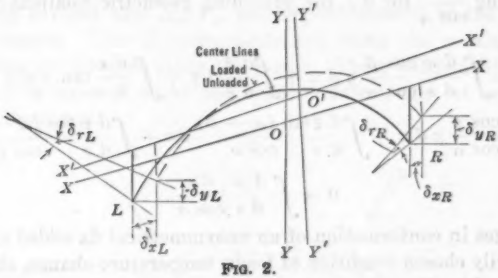

FIG. 2.

Consider a differential length of the arch rib, $ds$, the abscissa of which is $x$. The angle change within this differential length, due to the strained condition of the arch, is $d\phi$. The rate of angle change then is given by $\frac{d\phi}{ds}$.

The relative movement of $O_{Lx}$ and $O_{Rx}$ in the direction of the $x$-axis, due to the differential angle change, $\frac{d\phi}{ds}$, is equal to $\frac{d\phi}{ds} y \cos\beta\, ds$.

Denote the shortening of a differential length, $ds$, the abscissa of which is $x$, by $d\xi$. Hence, the shortening (or lengthening) of the differential length in the $x$-direction will be $\frac{d\xi}{ds} \cos\alpha\, ds$, in which, $\alpha$ is the angle the arch axis makes with the $x$-axis.

Considering the sliding or shear deformation perpendicular to the arch axis in a length, $ds$, to be $d\tau$, the differential movement in the $x$-direction is found to be $\frac{d\tau}{ds} \sin\alpha\, ds$,

As a result of these considerations, the equation for the relative movement of $O_{Lx}$ and $O_{Rx}$ along the $x$-axis is,

$$\Delta l = \delta_{xR} - \delta_{xL} = \int \frac{d\phi}{ds} y \cos\beta\, ds + \int \frac{d\xi}{ds} \cos\alpha\, ds + \int \frac{d\tau}{ds} \sin\alpha\, ds - (y'_L\, \delta_{rL} - y'_R\, \delta_{rR}) \cos\beta \quad \ldots\ldots\ldots\ldots (1)$$

Similarly, it may be shown that the relative movement of $O_{Ly}$ with respect to $O_{Ry}$ along the y-axis is,

$$\Delta l' = \delta_{yR} - \delta_{yL} = \int \frac{d\,\phi}{d\,s} x \cos\beta\, d\,s + \int \frac{d\,\xi}{d\,s} \sin(\alpha - \beta)\, d\,s + \int \frac{d\,r}{d\,s} \cos(\alpha - \beta)\, d\,s - (x'_L\, \delta_{rL} - x'_R\, \delta_{rR}) \cos\beta \quad \ldots\ldots(2)$$

The rotation of the left springing with respect to the right springing is,

$$\Delta r = \delta_{rR} - \delta_{rL} = \int \frac{d\,\phi}{d\,s} d\,s \quad \ldots\ldots(3)$$

Equations (1), (2), and (3) define the changed configurations of the arch due to all possible causes. These relations are geometrical and are independent of the properties of the material or conditions of equilibrium.

Considering that there is no translation or rotation of the ends of the arch, and substituting $\frac{dx}{\cos\alpha}$ for $d\,s$, the preceding geometric relations reduce to the forms,

$$\left.\begin{aligned} 0 &= \int \frac{d\,\phi}{d\,s} \frac{\cos\beta}{\cos\alpha} y\, d\,x + \int \frac{d\,\xi}{d\,s} d\,x + \int \frac{d\,r}{d\,s} \tan\alpha\, d\,x \\ 0 &= \int \frac{d\,\phi}{d\,s} \frac{\cos\beta}{\cos\alpha} x\, d\,x + \int \frac{d\,\xi}{d\,s} \frac{\sin(\alpha - \beta)}{\cos\alpha} d\,x + \int \frac{d\,r}{d\,s} \frac{\cos(\alpha - \beta)}{\cos\alpha} d\,x \\ 0 &= \int \frac{d\,\phi}{d\,s} \frac{d\,x}{\cos\alpha} \end{aligned}\right\} \quad \ldots\ldots(4)$$

The changes in conformation of an unsymmetrical fix-ended arch subjected to an arbitrarily chosen condition of loads, temperature change, shrinkage, etc., are thus defined by Equations (4).

For a symmetrical arch these equations may be written in the form:

$$\left.\begin{aligned} 0 &= \int \frac{d\,\phi}{d\,s} \frac{y\, d\,x}{\cos\alpha} + \int \frac{d\,\xi}{d\,s} d\,x + \int \frac{d\,r}{d\,s} \tan\alpha\, d\,s \\ 0 &= \int \frac{d\,\phi}{d\,s} \frac{x\, d\,x}{\cos\alpha} + \int \frac{d\,\xi}{d\,s} \tan\alpha\, d\,x + \int \frac{d\,r}{d\,s} d\,x \\ 0 &= \int \frac{d\,\phi}{d\,s} \frac{d\,x}{\cos\alpha} \end{aligned}\right\} \quad \ldots\ldots(5)$$

*Relations Defining Static Equilibrium.*—An unsymmetrical arch (Fig. 3) is subjected to an arbitrary system of loading, $P_1$, $P_2$, $P_n$, in the plane of the arch, with reactions, $R_L$ and $R_R$, occurring at the left and right ends of the arch, respectively. Fig. 3 shows the arch under load and in its deformed state.

The arch has been made statically determinate with respect to the external forces and reactions in Fig. 4, while at the same time it is held in its deformed state by forces applied to the ends of rigid lever arms which are fixed to the left and right springings respectively, and terminate at the center of coordinates. The arch in its deformed state is held in equilibrium by a system of forces which may be divided into two classes, namely, (1) statically determinate forces and reactions, and (2) redundant forces.

The statically determinate forces and reactions are, respectively, the applied loads, $P_1$, $P_2$, $P_n$, and the reactions, $V_L$, $V_R$, and $H_R$. The reaction, $H_R$, is a

quasi-horizontal force having its point of application at the right end of the arch and its direction parallel to the $x$-axis. The statically determinate forces may be considered as an independent system holding the structure in equilibrium. These are independent of internal stresses in the arch caused by deformations. Thus,

$$\Sigma H_R = \Sigma H_n$$
$$V_L + V_R = \Sigma V_n$$
$$\Sigma M \text{ (due to } P) = \Sigma M \text{ (due to reactions)}$$

On the other hand, the redundant forces are caused by restrained conditions of the ends of the arch and are directly caused by temperature changes, rib-shortening, movement of abutments, etc. The components of these forces must exist in pairs equal in magnitude and opposite in sense, for unless this is true the structure will not be maintained in a state of equilibrium. The redundant forces required to hold the structure in the conformation assumed are arbitrarily divided into $H_0$, $V_0$, and $M_0$-components at the center of the co-ordinate system. The $H_0$-components act along the $x$-axis, whereas the $V_0$-components are directed along the $y$-axis. These components may be considered to act in pairs of equal and opposite forces, one set acting upon the end of each lever arm.

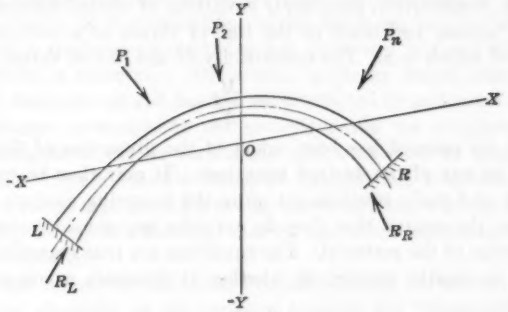

FIG. 3.

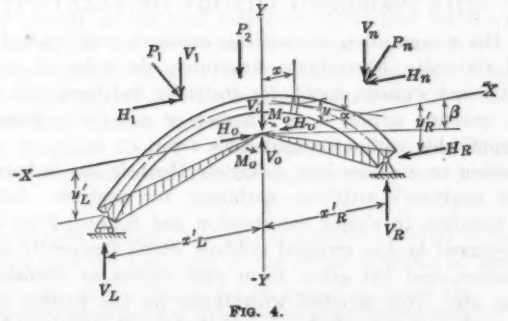

FIG. 4.

It is well to remember, comparing Figs. 3 and 4, that the resultant of the components, $H_0$, $V_0$, and $M_0$, at the end of the left lever arm, combined with

the vertical reaction, $V_L$, is the reaction, $R_L$. Similarly, the resultant of the components considered to act at the end of the right lever arm and the reactions, $V_R$ and $H_R$, form the reaction, $R_R$.

Consider, now, a normal section through the arch axis, having the abscissa, $x$. The stress functions due to the statically determinate forces will be denoted by a subscript, $d$; functions due to redundant forces will be denoted by a subscript, $i$. Hence, the moment at a section of the arch having the abscissa, $x$, will be given by $M_x = M_{xd} + M_{xi}$. Thus, considering the sense of the redundant forces on the left lever arm, the moment, normal thrust, and shear, respectively, are found to be:

$$\left.\begin{aligned} M_x &= M_{xd} + M_0 + V_0 x \times \cos\beta - H_0 y \times \cos\beta \\ N_x &= N_{xd} + H_0 \times \cos\alpha + V_0 \times \sin(\alpha - \beta) \\ S_x &= S_{xd} + H_0 \times \sin\alpha + V_0 \times \cos(\alpha - \beta) \end{aligned}\right\} \quad \ldots\ldots\ldots (6)$$

For the case of a symmetrical arch referred to a rectangular system of co-ordinates, Equations (6) become:

$$\left.\begin{aligned} M_x &= M_{xd} + M_0 + V_0 x - H_0 y \\ N_x &= N_{xd} + H_0 \times \cos\alpha + V_0 \times \sin\alpha \\ S_x &= S_{xd} + H_0 \times \sin\alpha + V_0 \times \cos\alpha \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (7)$$

Equations (6) for the unsymmetrical arch and Equations (7) for the symmetrical arch, respectively, are simply equations of statics defining the magnitude, line of action, and sense of the line of thrust at a section of the arch the abscissa of which is $x$. The eccentricity of the line of thrust is,

$$z' = \frac{M_x}{N_x} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Thus far, no account has been taken of the properties of the material of construction in any of the derived equations. It may then be concluded that the geometric and static relations set up in the foregoing analysis are not open to question on the ground that they do not take into consideration the correct elastic properties of the material. The equations are true regardless of whether the material is elastic, plastic, or whether it possesses a composite of both properties.

## II.—THE PROPOSED THEORY OF ELASTICITY

While in the computation of bending moments and the action of outer forces on all statically determinate structures, the rules of statics may be applied directly and without doubt, for statically indeterminate structures of concrete, the question arises as to whether or not the ordinary theory of elasticity is applicable without considerable error.

It is appalling to consider how definitely Hooke's law is ingrained in all the structural engineer's artificial machinery for analysis. Indeed, he has started with members in simple compression and flexure; from their mathematical development he has grouped symbols which frequently appear in the same combination, and has given them such names as moment of inertia, elastic weight, etc. Not satisfied with these, he has further superimposed laws governing the relation of these symbols to each other, and has evolved such combinations as Maxwell's law of reciprocal deflections, the theorems

of virtual work, methods of substitute beams, moment areas, slope deflections, and others. All these methods and theorems are developed assuming the variation of stress with strain to be governed by Hooke's law.

The assumption of a constant elastic modulus is correct for steel within the elastic limit, at least as far as designs subjected only to static loads are concerned. However, for concrete, this assumption is known to be incorrect and has resulted in much controversy. Many have doubted the applicability of the ordinary theory of elasticity to indeterminate concrete structures. To be sure, experiments are recorded indicating that the theory of elasticity gives results at least approximately correct for short-time loads. From a group of experiments performed on concrete frames,[3] M. Abe, M. Am. Soc. C. E., concludes that, "the elastic action of the frames under external load and the manner of stress distribution along members of the frame agree fairly well with the analysis given." (Dr. Abe's analysis was an application of a form of the ordinary theory of elasticity.[4]) Theoretical studies of the "Austrian Experiments on Arches"[5] indicates that the theory of elasticity, at least for loads within the working stresses of the material, gives reasonable results in a stress analysis for rubble masonry and brick arches as well as for concrete arches.

However, considering the degree of precision obtained by the ordinary theory of elasticity, it is unscientific, to say the least, not to determine what effect a variable modulus of elasticity has upon the moment and stress distribution within a structure. Of course, a theory based merely upon the properties of the material and not yet substantiated by at least a few scientific tests upon simple structures is not entirely ready for complete acceptance. Yet, no investigations are so unscientific and unreliable as those made upon built-up units, before a feasible theory of analysis has been developed. It is these considerations that have led the writer to develop what he believes to be a more flexible theory of elasticity, that is, one which accounts for a variable modulus of elasticity.

It is of some interest to note that Professor Melan (in studies to determine the modulus of elasticity of the concrete forming the "Stampf-Beton" arches tested by the Austrian Committee) found that the computed elastic modulus changed very greatly as the load increased, being less for the greater loads. His work was carried out by taking the actual vertical and horizontal displacements into account in an ordinary elastic analysis. Thus, one might conclude that the study of deformations in themselves have little meaning in the investigation of stresses in arches.

*Basis for Proposed Theory.*—After studying the stress-strain relation of considerable experimental data for concrete, the writer has chosen the equation,

$$\epsilon = k\,\sigma^m \qquad (9)$$

to define the relation. Bach[6] developed an equation similar to this except that instead of $k$ he used the reciprocal of the initial modulus of elasticity. How-

[3] *Bulletin No. 107*, Univ. of Illinois Eng. Experiment Station, p. 100.

[4] Assuming stress proportional to strain and no plastic deformations.

[5] Bericht des Gewölbe-Ausschusses, *Zeitschrift* des Oesterr. Ingenieur- und Architekten-Vereines, 1896.

[6] Bach and Bauman, "Elastizität und Festigkeit," Berlin, 1924.

ever, this expression did not prove as satisfactory to the writer and is less flexible in application. Bach and Schüle[7] through a large number of experiments found the exponent, $m$, in their equation to range between the limits of 1.10 and 1.16 for various mixes of concrete.

For concrete which was made into tension and compression specimens at the same time it was found that the elastic modulus in tension[8] did not differ greatly from that in compression, loads being applied in steps for the first time. This relation does not necessarily follow in all cases, but seems to be true in general for loads applied for the first time.

Data obtained from typical experiments by Dr. E. Probst[9] have been used by the writer as a basis for analysis in the basic equation, and curves (not herein included) were found which fit the data exceedingly accurately. The data included were for concrete 70 days old and of a 1 : 2 : 4 mix made with 10.1% water, giving a "very plastic material." Using the English system of units, for compression, the data are defined by,

$$\varepsilon = 178 \times 10^{-9}\ \sigma^{1.105}$$

In tension, the elasticity of the specimens used is represented by,

$$\varepsilon = 192 \times 10^{-9}\ \sigma^{1.03}$$

*Development of Proposed Theory of Elasticity for Flexure.*—When analyzing a concrete structure, it is hopeless to get a theory that is altogether exact. However, close approximations may be made, resulting in a study which will approach the actual conditions. Concrete in tension will follow a slightly different law for the relation of stress to deformation from that followed in compression. However, the general exponential relation is close for both. If the permanent set be included in the deformation represented in the exponential equation, then the equation, based on Probst's experiments, is practically the same for tension and compression.

Based upon these considerations, a theory of analysis is developed which accounts for a variation of the modulus of elasticity with variation in stress.

Structures are grouped into two classes, namely, (1) those subjected to pure flexure; and (2) those subjected to combined flexure and compression.

*Development of the Flexure Equations According to the Proposed Theory of Elasticity.*—The relation between elastic deformation and stress is given by,

$$\varepsilon = k\,\sigma^m \qquad (9)$$

Fig. 5 indicates a beam loaded in an arbitrary manner. Consider a differential length, $d\,s$. The section of the beam (Fig. 6($a$)) is assumed rectangular, having a width, $b$, and depth, $d$, or $2c$.

Let, $A = b\,d$ = the area of the section. By the principles of statics,

$$M = \int \sigma_z\, z\, d\, A$$

or, considering $\sigma_z$ to be independent of $b$,

$$M = \int_{-c}^{c} b\,\sigma_z\, z\, d\, z = 2\,b \int_0^c \sigma_z\, z\, d\, z \qquad (10)$$

[9] "Einfluss der Armature und der Risse im Beton auf die Tragsicherheit," E. Probst, *Mitteilungen* aus dem Königlichen Materialprüfungsamt zu Gross-Lichterfelde West, Ergänzungsheft I, pp. 8-14, Verlg. von Julius Springer, 1907.

A transformation of Equation (9) shows that,

$$\sigma_z = \left(\frac{\varepsilon_z}{k}\right)^{\frac{1}{m}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

From Fig. 6(*b*), it may be seen that, assuming conservation of plane sections during bending,

$$\varepsilon_z = z\,\frac{d\,\phi_E}{d\,s} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Combining Equations (10), (11), and (12), and rewriting,

$$M = \frac{2\,b}{k^{\frac{1}{m}}}\left(\frac{d\,\phi_E}{d\,s}\right)^{\frac{1}{m}} \int_0^c z^{\frac{1+m}{m}}\,d\,z$$

from which, when integrated and transformed,

$$\frac{d\,\phi_E}{d\,s} = \frac{k\,M^m}{\left[\dfrac{2\,m}{1+2\,m}\,b\,c^{\frac{1+2\,m}{m}}\right]^m}$$

or,

$$\frac{d\,\phi_E}{d\,s} = k\left(\frac{M}{Q}\right)^m \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

in which,

$$Q = \frac{2\,m}{1+2\,m}\,b\,c^{\frac{1+2\,m}{m}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

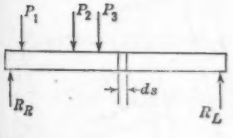

FIG. 5.

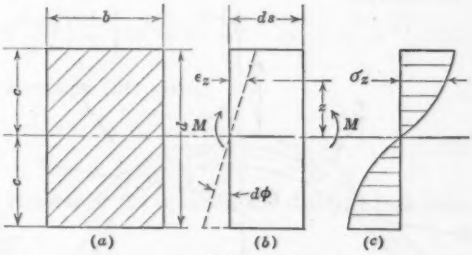

FIG. 6.

Equation (13) defines the rate of angle change at a section of a rectangular beam in terms of the bending moment, dimensions of the section, and elastic properties of the material.

*Special Case in Which $m = 1$.*—Assuming that $m = 1$, as in the ordinary theory of elasticity,

$$Q = \frac{2}{3}\,b\,c^3 = \frac{1}{12}\,b\,d^3 = I$$

and,

$$\frac{d\,\phi_E}{d\,s} = \frac{M}{E\,I}$$ [10]

[10] The value, $E$, is here assumed to be equal to $\frac{1}{k}$. As a matter of fact, $k$ should be chosen from experimental data and a value differing somewhat from this will better suit the data.

## Derivation of Proposed Theory of Elasticity for Arches

*General Relations.*—A method of analysis in which account is taken of the fact that strain is an exponential function of the stress becomes somewhat complicated because the law of superimposition of stresses and strains does not apply; that is, in order to reach the final stress and strain condition, one may not combine the results obtained by considering separately the effects of individual components of a force system. For example, consider a member in simple flexure. The total bending moment, $M$, is equal to the sum of the bending moments due to the individual loads, $P_1$, $P_2$, ...., $P_n$, or $M = M_1 + M_2 .... + M_n$. The rate of angle change at any section is,

$$\frac{d\,\phi_E}{d\,s} = k\left(\frac{M}{Q}\right)^m = k\,\frac{(M_1 + M_2 + .... + M_n)^m}{Q^m}$$

This equation can not be simplified to a form,

$$\frac{d\,\phi_E}{d\,s} = \frac{M_1}{E\,I} + \frac{M_2}{E\,I} + .... + \frac{M_n}{E\,I}$$

as in the ordinary theory of elasticity. As a result, when dealing with statically indeterminate structures, it is necessary to handle the entire force system in a single analysis.

Since shear deformations have only slight effect on the change in conformation of a loaded arch rib in comparison to the effects of moment and rib-shortening deformations, the deformations due to shear will be neglected in the analysis.

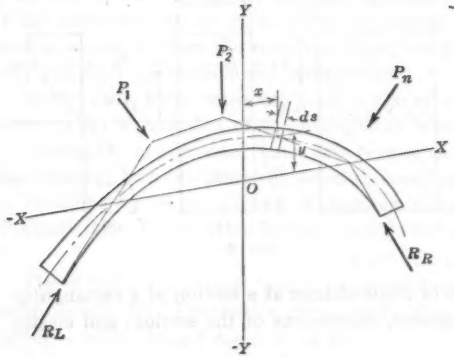

FIG. 7.

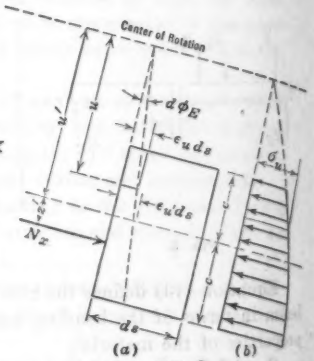

FIG. 8.

*Derivation of Equations.*—Consider the differential length, $d\,s$, of an arch rib (Fig. 7) loaded in an arbitrary manner. The rib is assumed to be rectangular in section. The width of the section is $b$, and the depth is $d$ or $2c$.

In Fig. 8($a$) the line of action of the normal thrust is $N_x$, and the deformed segment is $d\,s$. The distribution of stresses across the section is indicated in Fig. 8($b$).

The relation of strain to stress is given by,

$$\varepsilon_u = k\,\sigma_u^m \qquad (15)$$

By geometry (Fig. 8(a)),

$$\varepsilon_u = u \frac{d\,\phi_E}{d\,s} \quad \ldots\ldots (16)$$

Subtracting Equation (16) from Equation (15) and re-arranging terms,

$$\sigma_u = \left(\frac{u}{k} \times \frac{d\,\phi_E}{d\,s}\right)^{\frac{1}{m}} \quad \ldots\ldots (17)$$

The following relations must be true in order to maintain static equilibrium:

$$N_x\,(u' + z') = \int \sigma_u\, u\, d\,A \quad \ldots\ldots (18)$$

$$N_x = \int \sigma_u\, d\,A \quad \ldots\ldots (19)$$

By substituting $b \times d\,u$ for $d\,A$, the differential area of the section, and the value found in Equation (17), for $\sigma_u$, Equation (19) becomes,

$$N_x\,(u' + z') = \frac{b}{k^{\frac{1}{m}}} \times \left(\frac{d\,\phi_E}{d\,s}\right)^{\frac{1}{m}} \int_{(u'-c)}^{(u'+c)} u^{\frac{1+m}{m}}\, d\,u$$

from which,

$$N_x(u' + z') = \frac{m}{1+2m} \times \frac{b}{k^{\frac{1}{m}}} \times \left(\frac{d\,\phi_E}{d\,s}\right)^{\frac{1}{m}} \left[(u' + c)^{\frac{1+2m}{m}} - (u' - c)^{\frac{1+2m}{m}}\right] \quad (20)$$

Similarly, by making substitutions for $d\,A$ and $\sigma_u$ in Equation (19), and integrating between the same limits,

$$N_x = \frac{m}{1+m} \times \frac{b}{k^{\frac{1}{m}}} \times \left(\frac{d\,\phi_E}{d\,s}\right)^{\frac{1}{m}} \left[(u' + c)^{\frac{1+m}{m}} - (u' - c)^{\frac{1+m}{m}}\right] \quad (21)$$

Equation (20) divided by Equation (21) gives,

$$(u' + z') = \frac{1+m}{1+2m} \times \frac{\left[(u' + c)^{\frac{1+2m}{m}} - (u' - c)^{\frac{1+2m}{m}}\right]}{\left[(u' + c)^{\frac{1+m}{m}} - (u' - c)^{\frac{1+m}{m}}\right]} \quad \ldots\ldots (22)$$

Transposing $u'$ to the second member of the equation and dividing both members by $c$,

$$\frac{z'}{c} = \frac{1+m}{1+2m} \times \frac{\left[\left(\frac{u'}{c} + 1\right)^{\frac{1+2m}{m}} - \left(\frac{u'}{c} - 1\right)^{\frac{1+2m}{m}}\right]}{\left[\left(\frac{u'}{c} + 1\right)^{\frac{1+m}{m}} - \left(\frac{u'}{c} - 1\right)^{\frac{1+m}{m}}\right]} - \frac{u'}{c} \quad \ldots (23)$$

From Equation (21),

$$\frac{d\,\phi_E}{d\,s} = k \frac{N_x^m}{b\,c^{\frac{1+m}{m}} \frac{m}{1+m} \left[\left(\frac{u'}{c} + 1\right)^{\frac{1+m}{m}} - \left(\frac{u'}{c} - 1\right)^{\frac{1+m}{m}}\right]^m}$$

or,

$$\frac{d\,\phi_E}{d\,s} = k \left(\frac{N_x}{U}\right)^m \quad \ldots\ldots (24)$$

in which,

$$U = \left\{ b\,c^{\frac{(1+m)}{m}} \frac{m}{1+m} \left[\left(\frac{u'}{c} + 1\right)^{\frac{1+m}{m}} - \left(\frac{u'}{c} - 1\right)^{\frac{1+m}{m}}\right] \right\} \quad (25)$$

The rate of angle change in the arch at a radial section the abscissa of which is $x$, is given by Equation (24) in terms of the dimensions of the section, elastic properties of the material, magnitude of the normal thrust, and distance between the center of rotation and center of gravity of the section. Equation (23) shows the relation between the eccentricity of the thrust and the distance to the center of rotation. Thus, Equations (23) and (24) together fully define the angle change in terms of the moment, thrust, and properties of the section.

The rib-shortening, or the shortening at the gravity axis, of an elemental length, $d\,s$, is,

$$d\,\xi_E = \varepsilon_{u'}\,d\,s$$

but by geometry,

$$\varepsilon_{u'} = u'\,\frac{d\,\phi_E}{d\,s}$$

hence,

$$\frac{d\,\xi_E}{d\,s} = u'\,\frac{d\,\phi_E}{d\,s} \qquad \text{.....(26)}$$

Substituting for $\frac{d\,\phi_E}{d\,s}$, the value found in Equation (24),

$$\frac{d\,\xi_E}{d\,s} = u'\,k\left(\frac{N_x}{U}\right)^m \qquad \text{.....(27)}$$

Neglecting shear deformations and substituting values for $\frac{d\,\phi}{d\,s}$ and $\frac{d\,\xi}{d\,s}$, respectively, from Equations (24) and (27) into the geometric Equations (5),

$$\left.\begin{aligned} 0 &= \int k\left(\frac{N}{U}\right)^m \frac{y\,d\,x}{\cos\alpha} + \int u'\,k\left(\frac{N}{U}\right)^m d\,x \\ 0 &= \int k\left(\frac{N}{U}\right)^m \frac{x\,d\,x}{\cos\alpha} + \int u'\,k\left(\frac{N}{U}\right)^m \tan\alpha\,d\,x \\ 0 &= \int k\left(\frac{N}{U}\right)^m \frac{d\,x}{\cos\alpha} \end{aligned}\right\} \qquad \text{.....(28)}$$

By substituting $\frac{M}{z'}$ for $N$ in Equations (28), and replacing the definite integrals by summation of finite increments, the equations become,

$$\left.\begin{aligned} 0 &= k\sum\left(\frac{M}{z'\,U}\right)^m \frac{y\,\Delta\,x}{\cos\alpha} + k\sum u'\left(\frac{M}{z'\,U}\right)^m \Delta\,x \\ 0 &= k\sum\left(\frac{M}{z'\,U}\right)^m \frac{x\,\Delta\,x}{\cos\alpha} + k\sum u'\left(\frac{M}{z'\,U}\right)^m \tan\alpha\,\Delta\,x \\ 0 &= k\sum\left(\frac{M}{z'\,U}\right)^m \frac{\Delta\,x}{\cos\alpha} \end{aligned}\right\} \qquad \text{.....(29)}$$

*Special Case, $m = 1$.*—Equations (29) defining the proposed theory of elasticity for arches readily reduce to those of the ordinary theory of elasticity.

*Solution of Proposed Elastic Equations.*—Equations (29) fully define the elastic equilibrium of the arch, that is, its change in shape. However, a solution of these equations is not as simple as that when the ordinary straight-line, stress-strain variation is assumed. Angle changes in elementary radial

segments of the arch are dependent not only on the bending moment, but also on the eccentricity of the force producing the moment. No particular choice of the center of co-ordinates seems to aid materially in the analysis, because the deformations due to separate forces acting independently may not be superimposed to obtain the deformation caused by the combined system of forces.

Assume, now, the value of $m$ to be known from experiment. From Equation (23), values may then be computed showing the relation between the eccentricity, $z'$, of the compressive force, and the distance, $u'$, between the center of rotation and the gravity axis of the section. A more general relation is obtained by finding the relation between $\frac{z'}{c}$ and $\frac{u'}{c}$, because such a relation is directly applicable to a section of any thickness. Using constant values of $m$, curves have been plotted (Fig. 9) with $\frac{z'}{c}$ values as abscissas and $\frac{u'}{c}$ values as ordinates.

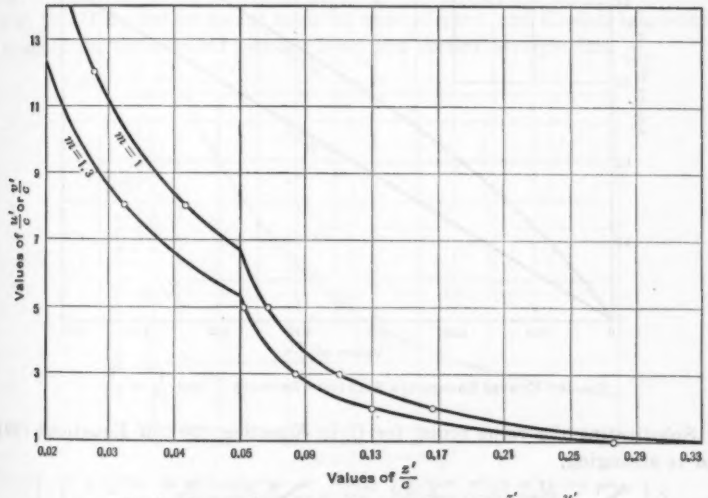

FIG. 9.—CURVES EXPRESSING RELATION BETWEEN $\frac{z'}{c}$ AND $\frac{u'}{c}$.

From Equation (25),

$$U = b\, c\, \frac{1+m}{m}\, U' \qquad (30)$$

in which,

$$U' = \frac{m}{1+m}\left[\left(\frac{u'}{c}+1\right)^{\frac{1+m}{m}} - \left(\frac{u'}{c}-1\right)^{\frac{1+m}{m}}\right] \qquad (31)$$

A relation of $\frac{1}{U'}$ and $\frac{z'}{c}$ is obtained between Equations (23) and (31) by substituting the same value of $\frac{u'}{c}$ in both equations and solving, respectively, for

the corresponding values of $\frac{1}{U'}$ and $\frac{z'}{c}$. Curves have been plotted (Fig. 10) with $\frac{z'}{c}$ values as abscissas and $\frac{1}{U'}$ values as ordinates. For $m = 1$, the curve is a straight line passing through the origin of co-ordinates. Hence, the expression, $\frac{1}{\frac{z'}{c}\, U'}$, is constant for all values of $z'$. Consequently, Equations (32), which have been derived from Equations (29), take the form of the ordinary theory of elasticity for $m = 1$.

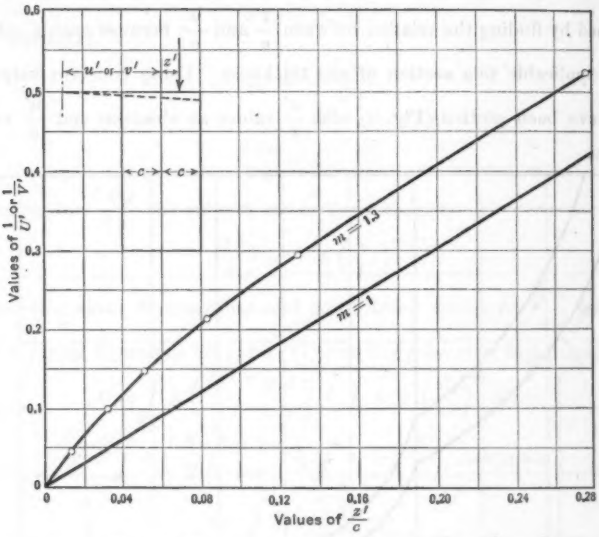

FIG. 10.—CURVES EXPRESSING RELATIONS BETWEEN $\frac{z'}{c}$ and $\frac{1}{U'}$ or $\frac{1}{V'}$.

Substituting the value found for $U$ in Equation (30) in Equations (29), and re-arranging,

$$\left.\begin{aligned} 0 &= k\left[\sum \frac{M_x^{\,m}}{\left(\frac{z'}{c}\,U'\right)^m} \frac{y\,\Delta x}{b^m\, c^{1+2m} \cos\alpha} + \sum \frac{u'}{c} \frac{M_x^{\,m}}{\left(\frac{z'}{c}\,U'\right)^m} \frac{\Delta x}{b^m\, c^{2m}}\right] \\ 0 &= k\left[\sum \frac{M_x^{\,m}}{\left(\frac{z'}{c}\,U'\right)^m} \frac{x\,\Delta x}{b^m\, c^{1+2m} \cos\alpha} + \sum \frac{u'}{c} \frac{M_x^{\,m}}{\left(\frac{z'}{c}\,U'\right)^m} \frac{\tan\alpha\,\Delta x}{b^m\, c^{2m}}\right] \\ 0 &= k \sum \frac{M_x^{\,m}}{\left(\frac{z'}{c}\,U'\right)^m} \frac{\Delta x}{b^m\, c^{1+2m} \cos\alpha} \end{aligned}\right\} \quad (32)$$

The factor, $k$, may be dropped, of course, from all these equations unless some element, such as shrinkage or temperature change, is taken into account.

Analyses of arches under various particular conditions of loading and deformation have been carried out by the proposed theory of elasticity, using Equations (32) and Figs. 9 and 10.

*Importance of Variable Modulus of Elasticity.*—The complexity of the angle changes in an arch is probably best realized by a few preliminary investigations. Upon first thought, one might conclude that the secant modulus for the average working stress can not be far wrong. However, the combined action of compression and bending moment introduces complications which are probably not immediately anticipated.

As an example, consider Fig. 11. The curve indicates the differential angle change at a given section due to a constant bending moment, the only variation being the eccentricity of the force producing the moment. It has been plotted on the basis of the exponential equation for the relation of stress to strain, considering $m = 1.3$. The ordinates are plotted as a constant, $f$, times $\frac{d\phi}{ds}$. The values of points on the curve are readily found by the aid of Fig. 10. If a constant secant modulus were adopted, and Hooke's law assumed to apply, the curve would take the form of a vertical straight line.

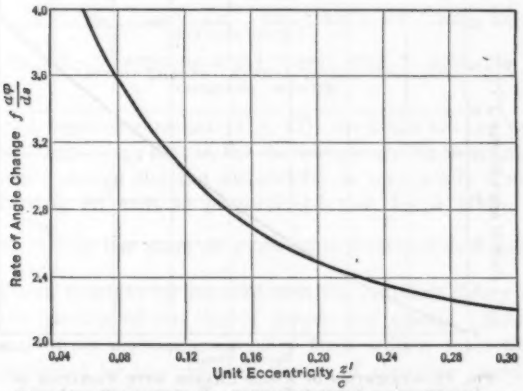

FIG. 11.—VARIATION OF ANGLE CHANGE WITH CHANGE IN ECCENTRICITY OF FORCE. MOMENT CONSIDERED CONSTANT. $m = 1.3$.

These considerations would indicate that no satisfactory study of the effect of a variable modulus of elasticity on the action of arches can be made, unless the eccentricity of the line of thrust as well as the bending moment is included in the analysis.

Consider a simple example solved by means of Fig. 11. No particular units will be kept in mind. Assume a load of 20 applied on a specimen, at an eccentricity, $0.06\,\frac{z'}{c}$. When $m = 1.3$, the rotation will be,

$$\phi = (20 \times 0.06)^{1.3} \times 3.95 = 5.00$$

Assume, now, that the same rotation is obtained, in a specimen of the same shape, but having $m = 1$ as an index of the stress-strain relation, for a load of 20 placed at the same eccentricity.

Now, consider the loads removed, and a load of 3 placed at an eccentricity, $0.26\frac{z'}{c}$, on both specimens. The rotation will be:

For $m = 1$,

$$\phi = 5.00 \times \frac{3 \times 0.26}{20 \times 0.06} = 3.25$$

and for $m = 1.3$,

$$\phi = (3 \times 0.26)^{1.3} \times 2.3 = 1.66$$

Hence, while the rotation in both specimens may be the same for one condition of loading, it may be quite different for another condition even though there is little change in bending moment. This analysis corresponds to taking a secant modulus for one case, that is, when $m = 1$, and the exponential formula in the other case.

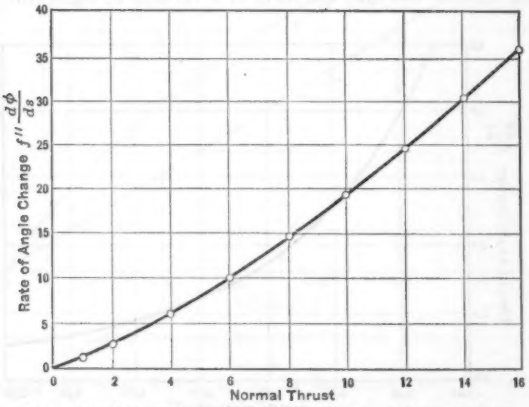

FIG. 12.—VARIATION OF ANGLE CHANGE WITH VARIATION OF INTENSITY OF NORMAL THRUST. ECCENTRICITY OF LINE OF THRUST CONSIDERED CONSTANT, $m = 1.3$.

A further investigation has been plotted in Fig. 12. The eccentricity of the line of thrust through a particular section was assumed to remain the same, while the normal thrust was considered to vary. The value of $m$ in the exponential formula was assumed to be equal to 1.3. The rate of angle change is plotted in terms of $\frac{d\phi}{ds}$ times a constant, $f''$.

Again, Fig. 13 shows the results of a study of the variation of angle change with the eccentricity of the line of thrust, considering the normal thrust to remain constant. The full line is drawn through points computed with the aid of Fig. 10; the broken line is a straight line drawn through the origin of

co-ordinates at a slope arbitrarily chosen to fit closely the computed curve. The rate of angle change is plotted as $\frac{d\phi}{ds}$ times a constant, $f'$.

A comparison of Figs. 11, 12, and 13 shows how the action of a structure may be anticipated. Fig. 12 indicates that the rate of angle change at a section increases more rapidly than the thrust, while Fig. 11 shows that, for a given moment, the rate of angle change decreases with an increase in eccentricity of the thrust producing the moment.

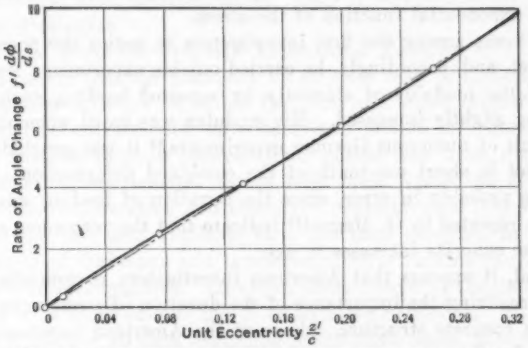

FIG. 13.—VARIATION OF ANGLE CHANGE WITH ECCENTRICITY OF LINE OF THRUST. NORMAL THRUST CONSIDERED CONSTANT. $m = 1.3$.

If the thrust remains constant (Fig. 13), the angle change varies almost directly as the eccentricity; that is, the curve representing the relation between the rate of angle change and the eccentricity is very nearly a straight line. Hence, considering an arch so proportioned that for a given loading the average stress, $\frac{N}{A}$, is the same on every normal section, and, neglecting rib-shortening effects, it might be expected that the ordinary theory of elasticity would give the location of the line of thrust very closely. However, if the average normal stress varies considerably from section to section, the line of thrust determined by the ordinary theory of elasticity could not be expected to be quite as accurate.

As a matter of fact the average compressive stress on the various normal sections throughout an arch of usual design does not vary to a large degree. For a uniformly loaded symmetrical parabolic arch, in which the sectional area increases as the secant of the angle between a tangent to the rib axis and the horizontal, the average compressive stress would be the same for every normal section.

## III.—PROPOSED THEORY OF PLASTICITY

That property of concrete by which the material undergoes a gradual but persistent deformation while in the condition of sustained stress, has been the subject of considerable discussion during the last decade. This phenom-

enon of plasticity, often referred to as "flow of concrete" or "time-yield", has been recognized by the early concrete experimenters, but only comparatively recently has it been given special attention in investigations.

In the proposed theory of elasticity the total strain is an exponential function of the stress and independent of the time interval of the stress. In contradistinction that group of mathematical relations which treats of the deformations in a structure where the total strain is a function of the duration as well as intensity of stress, has been arbitrarily termed the "theory of plasticity". As in the proposed theory of elasticity, this group of relations accounts for strain as an exponential function of the stress.

C. Bach[11] was among the first investigators to notice the phenomenon of permanent set, and, accordingly, he carried out his experiments for the determination of the modulus of elasticity by repeated loading, each successive loading being slightly increased. His modulus was based upon the rebound.

As a result of numerous German experiments,[12] it was concluded that the permanent set is about one-tenth of the combined deformation. The latter conclusion is probably in error, since the duration of loading was not great. Experiments reported by G. Magnel[13] indicate that the permanent set becomes smaller as the concrete increases in age.

In general, it appears that American investigators in concrete have been foremost in realizing the importance of the duration of stress upon the deformations in a concrete structure. Some of the American experiments will be discussed in detail.

*Proposed Exponential Equation of Plastic Deformation.*—Investigations in the plasticity of concrete, for the most part, have been of a qualitative, rather than quantitative, nature. The ultimate test of all experimental data on a material of engineering construction is the adaptability of such data to transformation into true mathematical laws which will define the properties of the material in such a manner that they may be accounted for in the analysis of complete structures.

Study of test data indicates that, while a mathematical law defining the plasticity of concrete must be expressed in three variables, it is closely given by an exponential equation involving the three variables, two of which are independent.

Investigations of a qualitative nature have been published by F. R. McMillan, A. H. Fuller, and H. F. Clemmer, Members, Am. Soc. C. E., and S. C. Hollister, Assoc. M. Am. Soc. C. E., as well as by Messrs. M. B. Lagaard, E. B. Smith, C. O. More, and others. The data made available by these experiments have been used by the writer as a comparison to the exponential equation,

$$\rho = K \sigma^p t^q$$

in which, $\rho$ is the plastic deformation which is a function of the unit stress and the time, $t$. The factor, $K$, is a parameter depending on the properties of the material. The exponents, $p$ and $q$, are constants which depend on the properties of the material at the beginning of the stressed condition.

[11] *Zeitschrift* des Vereines deutscher Ingenieure, 1895, p. 489.

[12] *Deutscher Ausschuss für Eisenbeton*, Heft 17 (1912), pp. 66–67.

[13] "Recherches experimentales sur le coefficient d'élasticité du béton," G. Magnel, *Revue Universelle des Mines*, Vol. 67, No. 1, 1924.

In proposing this equation, it is realized that the elastic and plastic properties of concrete vary considerably with the age of the material, especially during the first two or three months after it has been mixed. The values, $K$, $p$, and $q$, are intended to define the law of time-stress yield of the concrete during any time interval, provided the parameters satisfy the properties of the material at the beginning of the interval. The variable, $t$, is measured with its zero value at the instant that the load producing a stress, $\sigma$, is applied.

It will be observed that $p$ and $q$ are independent of the units of measurement of the stress, time, or deformation. Only $K$ will be affected by a change in the units of measure.

*Experimental Basis for Proposed Exponential Equation of Plastic Deformation.*—Assuming that the plasticity of concrete may be expressed in terms of an exponential equation in which the time and stress intensity are independent variables, experimental data have been plotted on logarithmic paper to find the variable relation between deformation and time, for a constant stress. Similarly, experimental values have been plotted to determine the relation between deformation and stress for constant time intervals.

Many of the test data available have not been compiled in such a way that the effects of shrinkage and temperature deformations can be separated from the plastic deformations. However, these effects in the data considered are believed to be small enough not to affect the conclusions. No attempt has been made to convert all data examined to the same units, because only $K$ is affected.

Time tests by Fuller and More[14] were performed on specimens presumably of approximately the same quality of concrete. The data have been plotted in Fig. 14. Specimens $A$ and $B$ were cylinders 8 in. in diameter, made from concrete mixed for use in building construction. Specimen $C$ was a block 8 in. square and 13 in. high, cut from a floor of the same building. All specimens were subjected to different loadings before applying a constant load over a long period of time. Tests on Cylinder $A$ were begun 101 days after pouring, and the time-yield test under a stress of 650 lb. per sq. in. was begun 24 days later. Cylinder $B$ was 137 days old when tests were begun; a constant load causing a stress of 1 150 lb. per sq. in. was applied after 6 days of variable load tests. Specimen $C$ was 131 days old, and the constant-load time-yield test was begun after 11 days, with a stress of 650 lb. per sq. in. No corrections have been made for temperature and moisture variations or for deformation due to shrinkage. However, comparatively little shrinkage will occur after 4 months, which time was the approximate age of the specimen. The tests having been made under laboratory conditions, it is believed that temperature and moisture variations were too small to affect the results materially.

No data were reported from which a relation between the intensity of stress and rate of deformation could be computed.

The exponential relation for time-yield for these experiments becomes,

$$\rho = f(\sigma^p)\, t^{0.42}$$

[14] "Time Tests of Concrete," by Fuller and More, *Proceedings*, Am. Concrete Inst., Vol. 12, p. 302, 1916.

In spite of the fact that all specimens were treated differently in the early stages of the load tests and one was loaded with a greater stress intensity than the others, all deformed approximately as the 0.42 power of the time. The theoretical curves shown in Fig. 14 fit the experimental points fairly closely.

Mr. Earl B. Smith made several tests[15] to determine the rate of yield of stressed concrete, part of which were on a reinforced concrete beam of 1:2:4 mix with gravel as the coarse aggregate. Reinforcement consisted of five ¼-in. rods. The beam was 5 in. wide, 8 in. deep, including 1-in. steel cover, and had a clear span of 10 ft. About two weeks after pouring, the beam was loaded at the center with a concentrated load of 1 225 lb. Deformations were measured at the top of the beam by means of a strain-gauge. Since, for loads considerably below the ultimate, the outer fiber stress in a concrete section of a beam is approximately proportional to the moment, the relation of deformation and stress was found approximately by comparing the moment with the deformation.

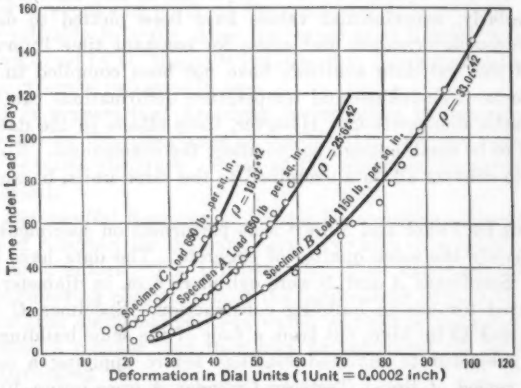

FIG. 14.—TIME-YIELD TESTS BY FULLER AND MORE. CURVES BY PROPOSED EXPONENTIAL FORMULA.

It is realized, of course, that such measurements would be true only if the plastic deformation varies directly as the stress. Since the plastic deformation appears to vary more nearly as the 1.3 power of the stress, there is likely to be a redistribution of stress over the section as the period of loading continues, the stress decreasing near the outer fiber and increasing near the neutral axis. The neutral axis will move down slightly, because the concrete continues to deform while the steel remains unchanged for a given stress. Hence, some error is introduced by assuming the outer fiber stress constant during a time-yield test. However, this should not seriously affect the general law which is being derived subject to confirmation by more precise experiments.

As the beam was only two weeks old when the test was started, considerable deformation was due to shrinkage. Correction was made for this by subtracting the deformation over the support from the recorded plastic flow throughout the span, for each time interval.

[15] "Flow of Concrete Under Sustained Loads," by E. B. Smith, *Proceedings*, Am. Concrete Inst., Vol. 13, p. 99, 1917; Vol. 12, p. 317, 1916.

The exponential equation, $\rho = K\ \sigma^p\ t^q$, for the concrete in Mr. Smith's test beam, takes the form,

$$\rho = 0.198\ \sigma^{1.73}\ t^{0.18}$$

in which, $\rho$ is the deformation in 0.0001 in., measured over an 8-in. length; $\sigma$ is the fiber stress measured in terms of the moment, in thousands of foot-pounds; and $t$ is the time of the period of stress, in days. A change to any other units of measure will simply change the coefficient of the second member of the equation.

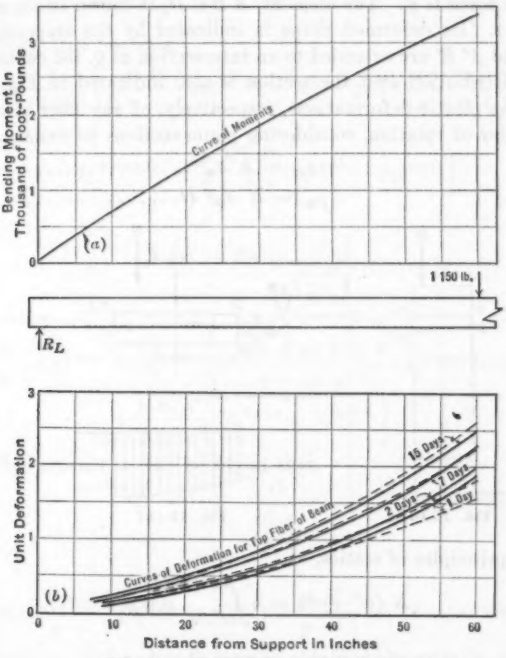

FIG. 15.—EXPERIMENTS BY E. B. SMITH.

The moment curve (Fig. 15(*a*)) is for combined dead and live loads. The graphs (Fig. 15(*b*)) have been plotted from experimental curves, indicated by Mr. Smith, by making correction for the shrinkage. Superimposed are a series of curves, in broken lines, indicating the plastic flow determined by the proposed exponential formula.

At the center of the beam, it will be noticed, the theoretical curves do not agree very closely with the experimental curves, especially for the short time intervals. It seems possible that this may be due in part to the localized effect of the concentrated load.

## DERIVATION OF EXACT EQUATIONS FOR THE PLASTIC THEORY

*General Requirements.*—As with the analysis for a variable modulus of elasticity, so for the proposed theory of plasticity—it is not possible to super-

impose the effects of individual forces separately upon a structure to obtain the effect of the combined system. In addition, the theory of plasticity presents further difficulty. Except in special cases, the elastic deformations and plastic deformations are dependent on each other; and, to be perfectly exact, the total deformation may not be written as the sum of two explicit functions of the elastic and plastic deformation, respectively.

*Derivation of Equations.*—Consider a column (Fig. 16(*a*)), measuring $b$ by $d$ in section, to be loaded by an eccentric normal force, $N$. The eccentricity of the force is $z'$. The element, $A\,B\,C\,D$, is shown in an enlarged scale in Fig. 16(*b*). Its deformed shape is indicated by the trapezoid, $A'\,B'\,C\,D$. Lines $A\,B$ and $A'\,B'$ are extended to an intersection at 0, the center of rotation. The stress distribution over the section is also indicated in Fig. 16(*b*). The elastic and the plastic deformations, respectively, of any fiber at a distance, $w$, from the center of rotation, considering plane sections to remain plane, are,

$$\epsilon_w = k\,\sigma_w^{m}. \qquad (33)$$

$$\rho_w = K\,\sigma_w^{p}\,t^{q}. \qquad (34)$$

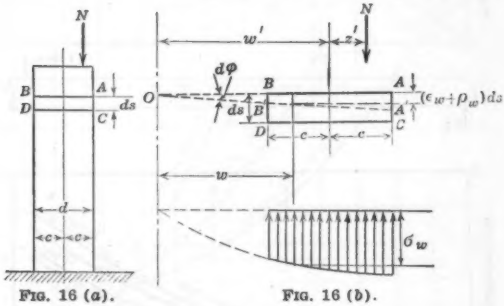

FIG. 16 (*a*). FIG. 16 (*b*).

From the principles of statics,

$$N\,(w' + z') = b\int_{w'-c}^{w'+c} \sigma\, w\, d\, w. \qquad (35)$$

and,

$$N = b\int_{w'-c}^{w'+c} \sigma\, d\, w. \qquad (36)$$

Thus, dividing Equation (35) by Equation (36),

$$(w' + z') = \int_{w'-c}^{w'+c} \sigma\, w\, d\, w \div \int_{w'-c}^{w'+c} \sigma\, d\, w. \qquad (37)$$

From the geometry of Fig. 16(*b*) and Equations (33) and (34),

$$\left.\begin{aligned} w\,\frac{d\,\phi}{d\,s} &= \epsilon_w + \rho_w = k\,\sigma_w^{m} + K\,\sigma_w^{p}\,t^{q} \\ w &= \frac{1}{\dfrac{d\,\phi}{d\,s}}\left[k\,\sigma_w^{m} + K\,\sigma_w^{p}\,t^{q}\right] \\ d\,w &= \frac{1}{\dfrac{d\,\phi}{d\,s}}\left[m\,k\,\sigma_w^{m-1} + p\,K\,\sigma_w^{p-1}\,t^{q}\right] \end{aligned}\right\} \qquad (38)$$

Considering $\frac{d\phi}{ds}$ a parameter, values of $w$ and $dw$ from Equations (38) substituted into Equations (35) and (36) result in,

$$N(w'+z') = \frac{1}{\left(\frac{d\phi}{ds}\right)^2}\int_{\sigma_2}^{\sigma_1}\sigma\,[k\,\sigma^m + K\,\sigma^p\,t^q]\,[m\,k\,\sigma^{m-1} + p\,K\,\sigma^{p-1}\,t^q]\,d\sigma$$

$$= \frac{1}{\left(\frac{d\phi}{ds}\right)^2}\left[\int_{\sigma_2}^{\sigma_1} m\,k^2\sigma^{2m}\,d\sigma + \int_{\sigma_2}^{\sigma_1}(m+p)\,k\,K\,t^q\,\sigma^{p+m}\,d\sigma + \int_{\sigma_2}^{\sigma_1} p\,K^2\sigma^{2p}\,t^{2q}\,d\sigma\right]$$

which when integrated becomes,

$$N(w'+z') = \frac{1}{\left(\frac{d\phi}{ds}\right)^2}\left[\frac{m\,k^2}{2\,m+1}(\sigma_1^{2m+1} - \sigma_2^{2m+1}) + \frac{(m+p)\,k\,K\,t^q}{(p+m+1)}(\sigma_1^{(p+m+1)} - \sigma_2^{(p+m+1)}) + \frac{p\,K^2\,t^{2q}}{2\,p+1}(\sigma_1^{2p+1} - \sigma_2^{2p+1})\right]$$

or,

$$N(w'+z') = \frac{F}{\left(\frac{d\phi}{ds}\right)^2} \quad \ldots\ldots(39)$$

in which,

$$F = \left[\frac{m\,k^2}{2\,m+1}(\sigma_1^{2m+1} - \sigma_2^{2m+1}) + \frac{(m+p)\,k\,K\,t^q}{p+m+1}(\sigma_1^{(p+m+1)} - \sigma_2^{(p+m+1)}) + \frac{p\,K^2\,t^{2q}}{2\,p+1}(\sigma_1^{2p+1} - \sigma_2^{2p+1})\right] \quad \ldots\ldots(40)$$

By a similar process it will be found that,

$$N = \frac{G}{\frac{d\phi}{ds}} \quad \ldots\ldots(41)$$

in which,

$$G = \frac{m\,k}{m+1}(\sigma_1^{m+1} - \sigma_2^{m+1}) + \frac{p\,K\,t^q}{p+1}(\sigma_1^{p+1} - \sigma_2^{p+1}) \quad \ldots\ldots(42)$$

From Equations (39) and (41) may be obtained the relation,

$$\frac{d\phi}{ds} = \frac{F}{G(w'+z')} \quad \ldots\ldots(43)$$

*Special Case, $t = 0$.*—Immediately after the load is applied, that is, the special case when $t = 0$, $w'$ becomes equal to $u'$ and Equation (43) reduces to,

$$\frac{d\phi_E}{ds} = k\,\frac{m+1}{2\,m+1}\,\frac{(\sigma_1^{2m+1} - \sigma_2^{2m+1})}{(\sigma_1^{m+1} - \sigma_2^{m+1})} \times \frac{1}{u'+z'} \quad \ldots\ldots(44)$$

but,

$$\sigma = \left(\frac{\varepsilon}{k}\right)^{\frac{1}{m}} \quad \ldots\ldots(45)$$

also,

$$\varepsilon_1 = (u'+c)\,\frac{d\phi_E}{ds} \text{ and } \varepsilon_2 = (u'-c)\,\frac{d\phi_E}{ds} \quad \ldots\ldots(46)$$

hence, from Equations (45) and (46),

$$\sigma_1 = \frac{\left[(u' + c)\frac{d\,\phi_E}{d\,s}\right]^{\frac{1}{m}}}{k^{\frac{1}{m}}} \text{ and } \sigma_2 = \frac{\left[(u' - c)\frac{d\,\phi_E}{d\,s}\right]^{\frac{1}{m}}}{k^{\frac{1}{m}}} \quad \ldots\ldots\ldots(47)$$

Substituting the values of $\sigma_1$ and $\sigma_2$ from Equations (47) into Equation (44) and re-arranging terms,

$$(u' + z') = \frac{m+1}{2\,m+1}\,\frac{\left[(u' + c)^{\frac{1+2m}{m}} - (u' - c)^{\frac{1+2m}{m}}\right]}{\left[(u' + c)^{\frac{1+m}{m}} - (u' - c)^{\frac{1+m}{m}}\right]} \quad \ldots\ldots\ldots(48)$$

which is identical with Equation (22) for the proposed theory of elasticity with $E$ introduced as a variable.

## Development of the Theory of Plasticity for the Arch

*General Assumptions.*—The total rate of angle change, $\frac{d\,\phi}{d\,s}$, given by Equation (43), is very complicated and would prove extremely unwieldy, if not impossible, to apply to a structure such as the concrete arch. The unknowns are in terms of the extreme fiber stresses which, according to the theory, will vary with time even should the load and eccentricity of the load remain constant.

To obviate this difficulty the following equation is introduced,

$$\frac{d\,\phi}{d\,s} = \frac{d\,\phi_E}{d\,s} + \frac{d\,\phi_P}{d\,s} \quad \ldots\ldots\ldots(49)$$

as a fundamental basis for further analysis. In this relation, $\frac{d\,\phi}{d\,s}$ is the total rate of rotation at a given section; $\frac{d\,\phi_E}{d\,s}$ is the rate of elastic rotation at the section; while $\frac{d\,\phi_P}{d\,s}$ is the rate of plastic rotation at the end of a particular time interval.

The theory, as here presented, is not quite exact, for it is developed on the assumption that the center of plastic rotation for each section is independent of the elastic properties of the concrete. To be perfectly exact, the center of plastic rotation at a section at the beginning of the stressed condition coincides with the center of elastic rotation, and moves toward the ultimate center of plastic rotation as the time interval of stress continues and redistribution of stresses within the section takes place. The theory is exact when the rate of change of elastic deformation with variation in stress is equal to the rate of change of plastic deformation (that is, when the parameters, $m$ and $p$, are equal), because in this case no redistribution of stresses takes place, and the center of elastic rotation coincides with the center of plastic rotation.

However, since the location of the ultimate center of plastic deformation approximates that of the center of elastic deformation for the probable range of values of $m$ and $p$, no large error is introduced by assuming that there is an instantaneous movement of the center of rotation from the elastic center to the ultimate plastic center.

The group of relations derived from Equation (49) will satisfy all the laws of statics and conditions of continuity; hence, they are mathematically correct. The term, $\frac{d\,\phi_E}{d\,s}$, of the second member of Equation (49) will be the same as for the proposed theory of elasticity.

Although the derivation which follows is for combined compression and flexure, Equation (49) may be expanded equally well for pure flexure.

*Derivation of Simplified Equations of Plasticity.*—Consider (Fig. 17(*a*)) an elementary radial segment, $d\,s$, of an arch. The center of the element is located at a point the abscissa of which is $x$. It is subjected to a normal thrust, $N_x$, acting at a distance, $z'$, from the centroidal axis.

An enlarged diagram of the element is indicated in Fig. 17(*b*). The elastic deformation of the segment is indicated by the trapezoid, $A\,B\,B'\,A'$; the plastic deformation is $A'\,B'\,B''\,A''$. Point $O$ is the center of elastic rotation, while Point $O'$ is considered to be the center of plastic rotation. Other nomenclature is indicated in the diagram.

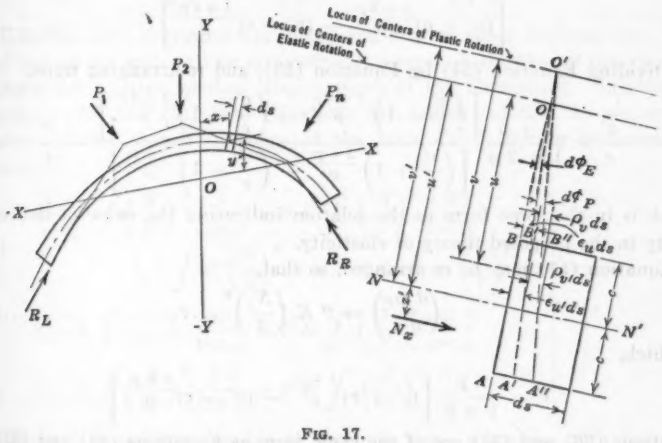

FIG. 17.

To determine $\frac{d\,\phi_P}{d\,s}$, the plastic deformation of a fiber at a distance, $v$, from the center of plastic rotation, $O'$, assuming stress distribution over the section to be dependent on the plastic properties of the material, is,

$$\rho_v = K\,\sigma_v^{\,p}\,t^q \qquad (50)$$

Geometric relations show that,

$$\rho_v = v\,\frac{d\,\phi_P}{d\,s} \qquad (51)$$

Eliminating $\rho_v$ between Equations (50) and (51), and re-arranging terms,

$$\sigma_v = \frac{1}{(t)^{\frac{q}{p}}}\left(\frac{v}{K}\,\frac{d\,\phi_P}{d\,s}\right)^{\frac{1}{p}} \qquad (52)$$

Since, for static equilibrium, the sum of the forces acting on the section in line with $n\,n'$ must be zero,

$$N_x = \int_{(v'-c)}^{(v'+c)} \sigma_v \, d\,A = \frac{b}{(t)^{\frac{q}{p}} K^{\frac{1}{p}}} \left(\frac{d\,\phi_P}{d\,s}\right)^{\frac{1}{p}} \int_{(v'-c)}^{(v'+c)} v^{\frac{1}{p}} \, d\,v$$

from which,

$$N_x = \frac{p}{1+p} \frac{b}{K^{\frac{1}{p}} t^{\frac{q}{p}}} \left(\frac{d\,\phi_P}{d\,s}\right)^{\frac{1}{p}} \left[(v' + c)^{\frac{1+p}{p}} - (v - c)^{\frac{1+p}{p}}\right] \ldots (53)$$

For equilibrium against static rotation,

$$N_x\,(v' + z') = \frac{b}{K^{\frac{1}{p}} t^{\frac{q}{p}}} \left(\frac{d\,\phi_P}{d\,s}\right)^{\frac{1}{p}} \int_{(v'-c)}^{(v'+c)} v^{\frac{1+p}{p}} \, d\,v$$

which, when integrated, becomes,

$$N_x\,(v' + z') = \frac{p}{1+2\,p} \frac{b}{K^{\frac{1}{p}} t^{\frac{q}{p}}} \left(\frac{d\,\phi_P}{d\,s}\right)^{\frac{1}{p}}$$

$$\left[(v' + c)^{\frac{1+2p}{p}} - (v' - c)^{\frac{1+2p}{p}}\right] \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

Dividing Equation (54) by Equation (53), and re-arranging terms,

$$\frac{z'}{c} = \frac{1+p}{1+2\,p} \frac{\left[\left(\frac{v'}{c}+1\right)^{\frac{1+2p}{p}} - \left(\frac{v'}{c}-1\right)^{\frac{1+2p}{p}}\right]}{\left[\left(\frac{v'}{c}+1\right)^{\frac{1+p}{p}} - \left(\frac{v'}{c}-1\right)^{\frac{1+p}{p}}\right]} - \frac{v'}{c} \ldots . (55)$$

which is in the same form as the relation indicating the value of the eccentricity in the proposed theory of elasticity.

Equation (53) may be re-arranged, so that,

$$\left(\frac{d\,\phi_P}{d\,s}\right) = t^q\,K \left(\frac{N_x}{V}\right)^p \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (56)$$

in which,

$$V = \frac{b\,p}{1+p} \left[(v' + c)^{\frac{1+p}{p}} - (v' - c)^{\frac{1+p}{p}}\right] \ldots\ldots\ldots\ldots (57)$$

Equations (56) and (57) are of the same form as Equations (24) and (25) in the proposed theory of elasticity. Equation (56) may also be written in the form,

$$\left(\frac{d\,\phi_P}{d\,s}\right) = t^q\,K \frac{M^p}{(z'\,V)^p} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (58)$$

The rib-shortening of the elemental length, $d\,s$, due to plastic flow, is,

$$d\,\xi_P = \rho_{v'}\,d\,s$$

Geometrically,

$$\rho_{v'} = v' \frac{d\,\phi_P}{d\,s}$$

hence,

$$\frac{d\,\xi_P}{d\,s} = v' \frac{d\,\phi_P}{d\,s}$$

or,

$$\frac{d\,\xi_P}{d\,s} = v'\,t^q\,K\left(\frac{N_x}{V}\right)^p \qquad (59)$$

The total rate of rotation at a section of the arch is now given by the expression,

$$\frac{d\,\phi}{d\,s} = \frac{d\,\phi_E}{d\,s} + \frac{d\,\phi_P}{d\,s}$$

or,

$$\frac{d\,\phi}{d\,s} = k\left(\frac{N_x}{U}\right)^m + t^q\,K\left(\frac{N_x}{V}\right)^p \qquad (60)$$

Also, the total rate of rib-shortening, is,

$$\frac{d\,\xi}{d\,s} = \frac{d\,\xi_E}{d\,s} + \frac{d\,\xi_P}{d\,s}$$

or,

$$\frac{d\,\xi}{d\,s} = u'\,k\left(\frac{N_x}{U}\right)^m + v'\,t^q\,K\left(\frac{N_x}{V}\right)^p \qquad (61)$$

Consider, now, a symmetrical arch, and neglect shear deformations. The dead load on the arch will be symmetrical; hence, rib-shortening can cause no tendency for relative vertical displacement of the abutments. Substituting Equations (60) and (61) into Equations (5), which indicate the geometrical relations of the change in shape of the arch, the following equations are obtained:

$$\left.\begin{aligned} 0 &= k\int\left(\frac{N}{U}\right)^m\frac{y\,d\,x}{\cos\alpha} + t^q\,K\int\left(\frac{N}{V}\right)^p\frac{y\,d\,x}{\cos\alpha} \\ &\quad + k\int u'\left(\frac{N}{U}\right)^m d\,x + t^q\,K\int v'\left(\frac{N}{V}\right)^p d\,x \\ 0 &= k\int\left(\frac{N}{U}\right)^m\frac{x\,d\,x}{\cos\alpha} + t^q\,K\int\left(\frac{N}{V}\right)^p\frac{x\,d\,x}{\cos\alpha} \\ 0 &= k\int\left(\frac{N}{U}\right)^m\frac{d\,x}{\cos\alpha} + t^q\,K\int\left(\frac{N}{V}\right)^p\frac{d\,x}{\cos\alpha} \end{aligned}\right\} \qquad (62)$$

While it is entirely possible to combine these equations with the static relations, the result would be exceedingly complicated. Since Maxwell's law of reciprocal deflections has no meaning in these equations, no simplification can be introduced by special arrangement of the co-ordinate system, or the like.

Equations (62) are derived on the basis of a statically determinate structure, that is, the location of the line of thrust in the arch must be known before the angle changes can be computed. For example,

$$t^q\,K\int\left(\frac{N}{V}\right)^p\frac{y\,d\,x}{\cos\alpha}$$

is the relative movement of the ends of the imaginary cantilevers terminating at the center of co-ordinates, along the $x$-axis.

Equations (62) may be solved with the aid of Figs. 9 and 10 in a manner similar to that explained for the proposed theory of elasticity.

*Effect of Plastic Flow in an Arch When $m = p$.*—If $m$ and $p$ are equal to the same number, $n$, that is, $n = m = p$, it will be found there are common values, $w$ and $w'$, such that $W = U = V$ and $w' = u' = v'$.

Equations (62) may then be written in the form,

$$\left.\begin{aligned} 0 &= (k + t^q K)\left\{\int_R^L \left(\frac{N}{W}\right)^n \frac{y\,d\,x}{\cos\alpha} + \int_R^L \left(\frac{N}{W}\right)^n w'\,d\,x\right\} \\ 0 &= (k + t^q K)\int_R^L \left(\frac{N}{W}\right)^n \frac{x\,d\,x}{\cos\alpha} \\ 0 &= (k + t^q K)\int_R^L \left(\frac{N}{W}\right)^n \frac{d\,x}{\cos\alpha} \end{aligned}\right\} \quad \ldots\ldots(63)$$

It will be noted from Equations (63) that, in case the exponents, $m$ and $p$, are equal, there can be no relative movement of the line of thrust due to plastic flow. Thus, although an arch undergoes a comparatively large amount of rib-shortening within a time interval, because of flow of the concrete, this is no reason for concluding that there has been a large redistribution of moments or stresses.

An actual structure, of course, presents greater complications than those indicated, for shrinkage, temperature changes, and live loads of varying intensity act in conjunction with the constant dead load pressures.

## The Theory of Plasticity for Pure Flexure

*General Equation.*—The rate of angle change at a section of a member subjected to both direct and flexural stresses is dependent on the intensity of the direct thrust as well as on the bending moment. Hence, Equation (49) takes a special form when developed for flexure alone.

A derivation of the flexure formulas for plasticity is similar to the development presented in the proposed theory of elasticity for flexure. It will be found that,

$$\frac{d\,\phi_P}{d\,s} = K\left(\frac{M}{S}\right)^p t^q \quad \ldots\ldots(64)$$

in which,

$$S = \frac{2\,p}{1 + 2\,p}\,b\,c^{\frac{1+2p}{p}} \quad \ldots\ldots(65)$$

Other terms in Equation (64) have been defined in the development of the theory of plasticity for arches.

Substituting the values of $\frac{d\,\phi_E}{d\,s}$ and $\frac{d\,\phi_P}{d\,s}$, found, respectively, in Equations (13) and (64), into Equation (49), the relation for the total rate of angle change becomes,

$$\frac{d\,\phi}{d\,s} = k\left(\frac{M}{Q}\right)^m + K\left(\frac{M}{S}\right)^p t^q \quad \ldots\ldots(66)$$

As in the case of the theory of plasticity for arches, this relation is physically exact only when $n = m = p$. In that case, $Z = Q = S$, and Equation (66) may be rewritten as,

$$\frac{d\,\phi}{d\,s} = (k + t^q K)\left(\frac{M}{Z}\right)^n \quad \ldots\ldots(67)$$

## IV.—ANALYSIS OF STRUCTURES IN PURE FLEXURE

Concrete structures designed for flexure can be economical only when combined with steel, for concrete has a very low tensile strength. However, if fiber stresses were kept sufficiently low, it would be entirely possible to design concrete beams to support loads by pure flexure.

What follows covers studies of beams composed of a material having elastic and plastic properties similar to that indicated by the experimental data on concrete, and shows their application to structures in pure flexure and the effects to be expected because of such phenomena as plastic flow. In addition, computations have been made indicating what effect a variable relation of stress to strain has on the distribution of stress and moments in a loaded structure.

No particular attempt has been made to choose exact constants to define the properties of the material in the exponential equations, but values have been chosen which will probably give the extreme conditions found in practice. Before very close values can be assigned to the parameters in the exponential equations, more precise experiments must be performed. This is especially true for the proposed plastic equations.

*Deflection of Simple Supported Beam with Concentrated Load at Center.*—Fig. 18 indicates a simple supported beam, of length, $l$, subjected to a concentrated load, $P$, at mid-span. The beam will be assumed to be 10 in. wide and 40 in. deep. Consider that both elastic and plastic deformations take place under the influence of the load, and that the parameters in the exponential equations have the following values: $m = p = n = 1.15$; $k = 183 \times 10^{-9}$; $K = 17 \times 10^{-9}$; and $q = 0.40$.

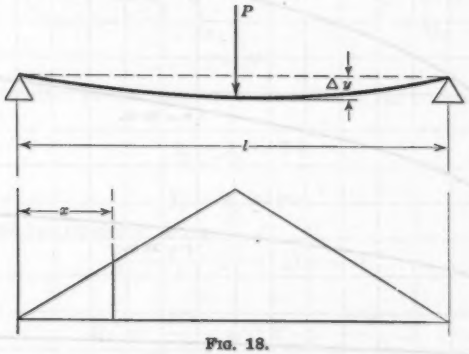

FIG. 18.

Since the beam is symmetrical, the tangent to the beam under the load will remain parallel to a line through the supports. Hence, the center deflection may be expressed by,

$$\Delta y = \int_0^{\frac{1}{2}l} \frac{d\phi}{ds} x \, dx$$

but,

$$\frac{d\,\phi}{d\,s} = (k + t^q\,K)\left(\frac{M}{Z}\right)^n$$

The bending moment at any point along the beam is,

$$M = \frac{1}{2}\,P\,x$$

hence,

$$\Delta\,y = (k + t^q\,K)\left(\frac{\frac{1}{2}\,P}{Z}\right)^n \int_0^{\frac{1}{2}\,l} x^{(1+n)}\,d\,x$$

Integrating and substituting numerical values, where given,

$$\Delta\,y = P^{1.15}\,\frac{(183 + 17\,t^{0.4})\,10^{-13}}{1\,135}\,t^{3.15}$$

In order that numerical results may be obtained, the length, $l$, of the beam will be considered to be 250 in. The last equation may then be rewritten as,

$$\Delta\,y = P^{1.15}\,(57.2 + 5.32\,t^{0.4})\,10^{-8}$$

The deflections at the ends of various time intervals and for different magnitudes of the concentrated load, are plotted in Fig. 19. The ordinates corresponding to the respective load concentrations on the line of zero abscissas measure the deflection at the center of the beam due to elastic deformations produced at the time the load is applied.

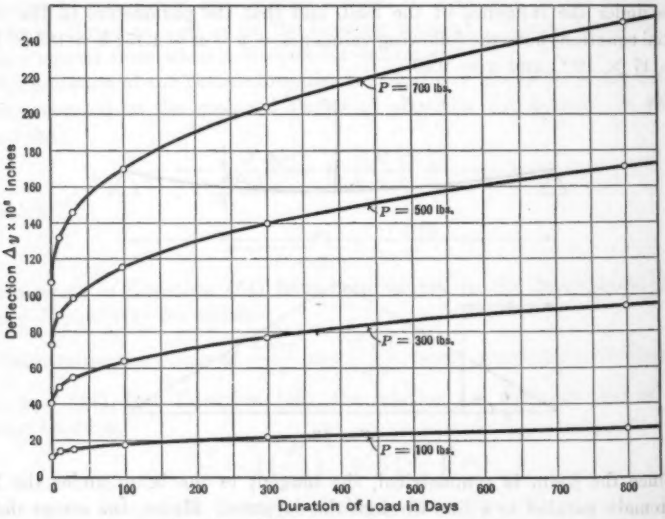

FIG. 19.—PLASTIC DEFLECTION OF BEAM.

*Beam Fixed at One End and Supported Unrestrained at the Other End.*—Consider the beam, $A\,B$ (Fig. 20 (*a*)). The moment diagram (Fig. 20 (*b*))

is made up of the moment diagram for a simple beam loaded with the force, $P$, and the diagram due to the fixing of the beam at $A$.

The mathematics involved in finding the moments is considerably simplified by replacing the moment and shear at $A$ (Fig. 20(c)) by a force, $R_L$ (for convenience in visualizing assumed to act upon the end of a rigid lever arm fastened to the beam at $A$), applied at the center of the rotation, such that,

$$M_A = R_L\,(a - x') \text{ and } V_A = R_L$$

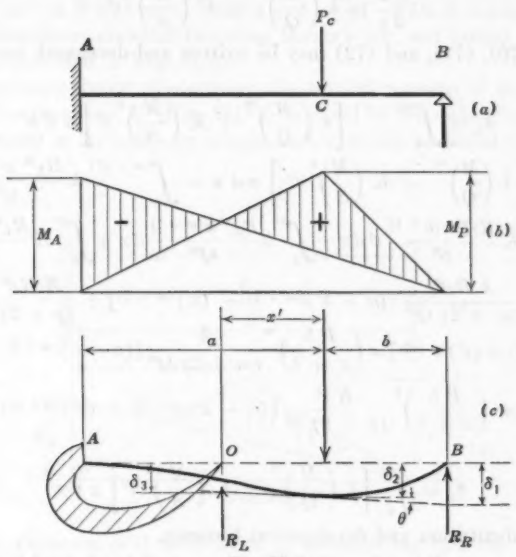

FIG. 20.

If $\theta$ is the rotation of the tangent to the beam at the concentrated load, $P$, by geometry,

$$\delta_2 = \delta_1 - \theta\, b$$

and,

$$\delta_2 = \delta_3 + \theta\, x'$$

Subtracting and re-arranging terms,

$$\delta_1 - \delta_3 - (x' + b)\,\theta = 0 \qquad (68)$$

By statics,

$$R_L = \frac{P\,b}{x' + b}; \text{ and } R_R = \frac{P\,x'}{x' + b} \qquad (69)$$

Since $\delta_3$ is the deflection of $O$ away from the tangent at $O$,

$$\delta_3 = \int_0^{(a-x')} \frac{d\,\phi}{d\,s}\, x\, d\,x + \int_0^{x'} \frac{d\,\phi}{d\,s}\, x\, d\,x \qquad (70)$$

Similarly, $\delta_1$ is the deflection of $B$ away from the tangent at $C$, hence,

$$\delta_1 = \int_0^{b} \frac{d\,\phi}{d\,s}\, x\, d\,x \qquad (71)$$

The slope of the tangent at $C$ is,

$$\theta = \int_{x'}^{(a-x')} \frac{d\,\phi}{d\,s}\, d\,x \qquad (72)$$

In Equations (70) and (72) the center of co-ordinates is at $O$; in Equation (71), $B$ is the center of co-ordinates.

Since,

$$\frac{d\,\phi}{d\,s} = k\left(\frac{M}{Q}\right)^m + K\left(\frac{M}{S}\right)^p t^q$$

Equations (70), (71), and (72) may be written and developed, respectively, as follows:

$$\delta_3 = \int_0^{(a-x')} \left[k\left(\frac{M}{Q}\right)^m + K\left(\frac{M}{S}\right)^p t^q\right] x\, d\,x$$

$$+ \int_0^{x'} \left[k\left(\frac{M}{Q}\right)^m + K\left(\frac{M}{S}\right)^p t^q\right] x\, d\,x = \int_0^{(a-x')} k\,\frac{R_L{}^m\, x^{(m+1)}}{Q^m}\, d\,x$$

$$+ \int_0^{(a-x')} K\,\frac{R_L{}^p\, x^{(p+1)}}{S^p}\, t^q\, d\,x + \int_0^{x'} k\,\frac{R_L{}^m x^{(m+1)}}{Q^m}\, d\,x + \int_0^{x'} K\,\frac{R_L{}^p\, x^{(p+1)}}{S^p} t^q dx$$

$$= \frac{k\,R_L{}^m}{(m+2)\,Q^m}\left[(a-x')^{(m+2)} + (x')^{(m+2)}\right] + \frac{K\,R_L{}^p\, t^q}{(p+2)\,S^p}$$

$$\left[(a-x')^{(p+2)} + (x')^{(p+2)}\right] = \left(\frac{P\,b}{x'+b}\right)^m \frac{k}{(m+2)\,Q^m}\left[(a-x')^{(m+2)} + (x')^{(m+2)}\right]$$

$$+ \left(\frac{P\,b}{x'+b}\right)^p \frac{K\,t^q}{(p+2)\,S^p}\left[(a-x')^{(p+2)} + (x')^{(p+2)}\right] \qquad (73)$$

also,

$$\delta_1 = \int_0^b \left[k\left(\frac{M}{Q}\right)^m + K\left(\frac{M}{S}\right)^p t^q\right] x\, d\,x$$

by similar substitution and development becomes,

$$\delta_1 = k\left(\frac{P\,b}{x'+b}\right)^m \frac{(x')^m\, b^2}{(m+2)\,Q^m} + K\left(\frac{P\,b}{x'+b}\right)^p \frac{(x')^p\, b^2\, t^q}{(p+2)\,S^p} \qquad (74)$$

Similarly,

$$\theta = \int_{x'}^{(a-x')} \left[k\left(\frac{M}{Q}\right)^m + K\left(\frac{M}{S}\right)^p t^q\right] d\,x$$

which becomes,

$$\theta = \left(\frac{P\,b}{x'+b}\right)^m \frac{k}{(m+1)\,Q^m}\left[(a-x')^{(m+1)} - (x')^{(m+1)}\right]$$

$$+ \left(\frac{P\,b}{x'+b}\right)^p \frac{K\,t^q}{(p+1)\,S^p}\left[(a-x')^{(p+1)} - (x')^{(p+1)}\right] \qquad (75)$$

By substituting the values from Equations (73), (74), and (75) into Equations (68), and collecting terms,

$$k\left[\frac{P\,b}{(x'+b)\,Q}\right]^m \left\{\frac{(x')^m\, b^2}{(m+2)} - \frac{\left[(a-x')^{m+2} + (x')^{m+2}\right]}{(m+2)}\right.$$

$$\left. - \frac{x'+b}{m+1}\left[(a-x')^{(m+1)} - (x')^{(m+1)}\right]\right\} + K\,t^q\left[\frac{P\,b}{(x'+b)\,S}\right]^p \left\{\frac{(x')^p\, b^2}{(p+2)}\right.$$

$$\left. - \frac{\left[(a-x')^{p+2} + (x')^{p+2}\right]}{(p+2)} - \frac{x+b}{p+2}\left[(a-x')^{p+1} - (x')^{p+1}\right]\right\} = 0 \qquad (76)$$

At the beginning of a loaded condition there is no plastic flow; $t = 0$, and hence,

$$\frac{(x')^m b^2}{(m+2)} - \frac{[(a-x')^{m+2} + (x')^{m+2}]}{(m+2)} - \frac{x'+b}{(m+1)}[(a-x')^{m+1} - (x')^{m+1}] = 0 \quad \ldots\ldots\ldots\ldots (77)$$

*Special Case, in Which $m = 1$ and $a = b = \frac{1}{2} l$.*—This is the condition of a beam of homogeneous material following Hooke's law, and loaded at mid-span. The beam is indicated in Fig. 21(*a*).

By the ordinary theory of elasticity, the statical moment of the area under the moment curve about $B$ (Fig. 21(*b*)) is equal to the deflection of $B$ away from the tangent at $A$, hence, by simple statics, it will be found that,

$$x' = \frac{5}{22} l$$

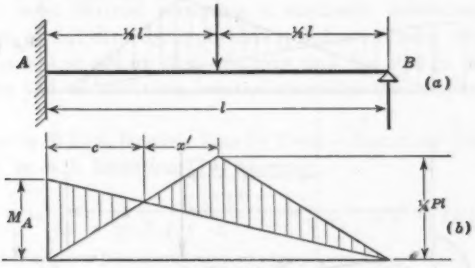

FIG. 21.

A test of Equation (77) is obtained by substituting into the equation the values of $c$ and $x'$ as obtained from the ordinary theory of elasticity. The first member of the equation reduces to zero, thereby verifying the derived equation.

*Special Case, in Which $m = 1.3$, and $a = b = \frac{1}{2} l$.*—This is an exaggerated case for concrete in which Hooke's law does not apply. The location of the point of contraflexure will be assumed to be the same as that found by the theory of elasticity (stress is proportional to strain). A substitution of the assumed values, $m = 1.3$, into Equation (77) again reduces the expression practically to an identity.

Thus, Equation (77) is satisfied for values of $m$ other than 1, without appreciably moving the point of contraflexure. Hence, one might conclude that the moments in the beam are not affected by static loads, although the modulus of elasticity of the material varies with the stress.

Further, an analysis of the first term of Equation (76) indicates that the flow of the material with the lapse of time does not change the moment distribution in the beam. It will be observed that both members of the first term contain factors similar to the first term of Equation (77). Hence, it may be concluded that Equation (76) will be satisfied by a value of $x'$ which would be obtained by the ordinary theory of elasticity in which Hooke's law is as-

sumed to be correct. This conclusion, of course, is on the basis of a homogeneous material.

Although the distribution of moments in the beam remains the same throughout any time interval, the distribution of stresses and the configuration of the beam will constantly change as the time interval increases.

*Beam Fixed at One End, Supported Unrestrained at the Other End, and Free Support Allowed to Settle a Distance, $\Delta y$.*—The support at $B$, in Fig. 22($a$), is assumed to settle an arbitrary amount, $\Delta y$, when the load, $P$, is applied.

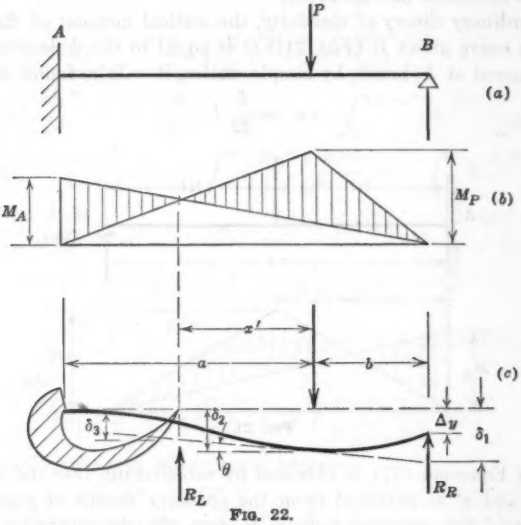

FIG. 22.

Equation (74) then takes the form,

$$\delta_1 = k\left(\frac{P\,b}{x'+b}\right)^m \frac{(x')^m\,b^2}{(m+2)\,Q^m} + K\left(\frac{P\,b}{x'+b}\right)^p \frac{(x')^p\,b^2\,t^q}{(p+2)\,S^p} + \Delta y$$

This results in a modification of Equation (76), which then may be written as,

$$t^q = \frac{-k\left[\frac{P\,b}{(x'+b)\,Q}\right]^m \left\{\frac{(x')^m\,b^2}{(m+2)} - \frac{[(a-x')^{m+2}+(x')^{m+2}]}{(m+2)} - \frac{x'+b}{(m+1)}[(a-x')^{m+1}-(x')^{m+1}]\right\} - \Delta y}{K\left[\frac{P\,b}{(x'+b)\,S}\right]^p \left\{\frac{(x')^p\,b^2}{(p+2)} - \frac{[(a-x')^{p+2}+(x')^{p+2}]}{(p+2)} - \frac{(x'+b)}{(p+1)}[(a-x')^{p+1}-(x')^{p+1}]\right\}} \quad \ldots(78)$$

A scrutiny of Equation (78) immediately discloses that the distribution of moments in the beam changes with the time. A state of equilibrium is approached as the time interval, $t$, becomes very large.

When $x'$ in Equation (78) becomes equal to the value of $x'$ which satisfies Equation (76), the denominator of the second member of Equation (78) becomes zero; hence, $t$ becomes infinite. This indicates that, with a lapse of time, the moment distribution in the beam approaches that of the beam without settlement of the support.

Immediately after the load, $P$, is applied with resulting settlement of support, $t = 0$; hence, Equation (78) takes the form,

$$k\left[\frac{P\,b}{(x'+b)\,Q}\right]^m \left\{\frac{(x')^m\,b^2}{(m+2)} - \frac{[(a-x')^{(m+2)} + (x')^{(m+2)}]}{(m+2)} - \frac{x'+b}{(m+1)}[(a-x')^{(m+1)} - (x')^{(m+1)}]\right\} + \Delta y = 0 \quad \ldots\ldots (79)$$

The distribution of moments then varies as a function of the time interval. The limiting values of $x'$ will be the value just after loading and settling of the support and the value for the conditions of no settlement of the support. The equations have been derived assuming a statically determinate condition, which, of course, is not directly applicable to indeterminate structures. That is, the equations are so set up that one may find the change in shape of the structure at the end of any time interval provided the moment distribution is known.

*Special Case in Which Hooke's Law Is True.*—Assuming that Hooke's law applies, that is, $m = 1$, Equation (79) becomes,

$$\Delta y = \frac{P\,b}{(x'+b)\,E\,I}\left\{\frac{x'\,b^2}{3} - \frac{1}{3}[(a-x')^3 + (x')^3] - \frac{1}{2}(x'+b)[(a-x')^2 - (x')^2]\right\} \quad \ldots\ldots (80)$$

*Numerical Case.*—As a simple case for the study of the effects of plastic flow, consider the beam in Fig. 23. The following values will be considered to satisfy the properties of the concrete in the exponential equations: $m = 1.15$; $p = 1.30$; $q = 0.40$; $K = 36 \times 10^{-9}$; and $k = 182 \times 10^{-9}$.

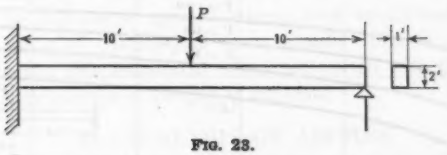

FIG. 23.

Assume that the right support settles at the instant of applying the load such that the right reaction is zero and the beam is just in contact with the support. In Equation (78) $x'$ will be equal to zero at the beginning of the loaded condition. Hence, the settlement of the support will be,

$$\Delta y = k\left(\frac{P}{Q}\right)^m\left[\frac{a^{(m+2)}}{m+2} + \frac{b\,a^{(m+1)}}{m+1}\right]$$

or, substituting the numerical values,

$$\Delta y = P^{1.15} \times 12 \times 10^{-6} \text{ in.}$$

Assume, now, that plastic flow takes place. Deformation will take place in the part of the beam that is subject to stress, and this will result in load being transferred to the right reaction which, it is assumed, is fixed in location, that is, it does not settle further.

Considering a given location of the point of contraflexure in the beam, a study will be made to determine the time interval required for the beam to assume a conformation which will satisfy its end conditions. Thus, when a load, $P$, is applied at the center of the beam and the deflection at the left support is $\Delta y = P^{1.15} \times 12 \times 10^{-6}$, the point of contraflexure might be considered to be directly under the load, since the moment is zero in the right half of the beam.

If the point of inflection is considered to be a distance, $x'$, to the left of the load, the time required for the slope of the beam at the left support to reach its normal condition may be computed by Equation (78), and would be,

$$t = \left\{ \begin{array}{l} -kS^p \int \left(\dfrac{b}{x'+b}\right)^m \left[\dfrac{(x')^m\, b^2}{m+2} - \dfrac{[(a-x')^{m+2} + (x')^{m+2}]}{m+2} \right. \\ \left. - \dfrac{x'+b}{m+1}[(a-x')^{m+1} - (x')^{m+1}]\right] + \left[\dfrac{a^{(m+2)}}{m+2} + \dfrac{b\,a^{(m+1)}}{m+1}\right] \Bigg\} \\ \hline K\, Q^m \left(\dfrac{b}{x'+b}\right)^p \int \left\{ \dfrac{(x')^p\, b^2}{p+2} - \dfrac{[(a-x')^{p+2} + (x')^{p+2}]}{p+2} \right. \\ \left. - \dfrac{x'+b}{p+1}[(a-x')^{p+1} - (x')^{p+1}] \right\} \end{array} \right\}^{\frac{1}{q}} \cdot \frac{P^{(m-p)}}{} \quad (81)$$

Equation (81) has been solved by substituting various numerical values for the distance, $x'$, and for the load, $P$. All computations for this analysis were made on an 8-in. slide-rule. A graphical representation of the results obtained by studying the movement of the point of contraflexure is shown on Fig. 24. Curves are plotted for various values of the concentrated loads, $P$.

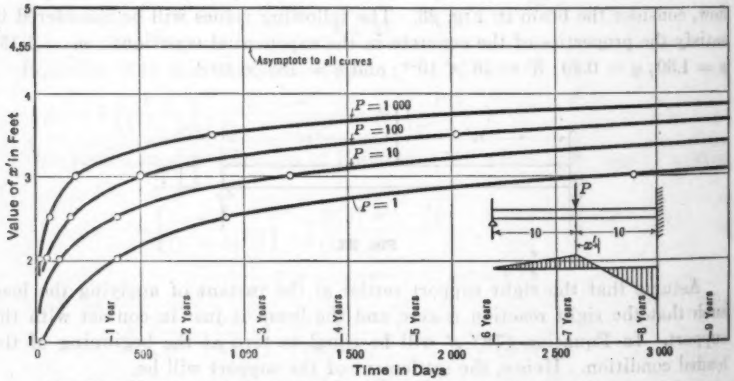

FIG. 24.—MOVEMENT OF POINT OF CENTER OF FLEXURE FOR CONCENTRATED LOAD.

A load of 1 000 lb. produces an extreme fiber stress about equal to the maximum tensile strength obtained in concrete.

When the point of contraflexure approaches a location 4.55 ft. from the center of the beam, the numerator in the second member of Equation (81)

becomes zero and the time interval becomes infinite. This "critical point" is at the point of contraflexure which would be found for the condition of pure elastic deformation and no settlement of the support. Fig. 24 shows a line through the critical point as the asymptote to all curves indicating the movement of the point of contraflexure.

The variation of moment distribution as $x'$ changes may readily be computed from simple static and geometric relations in the moment diagram. Curves have been plotted showing the moment redistribution in the beam in which the support has settled and plastic flow has occurred. Fig. 25 shows the curves considering, respectively, two different amounts of settlement of the support, $A$, and the load to be 1 000 lb.

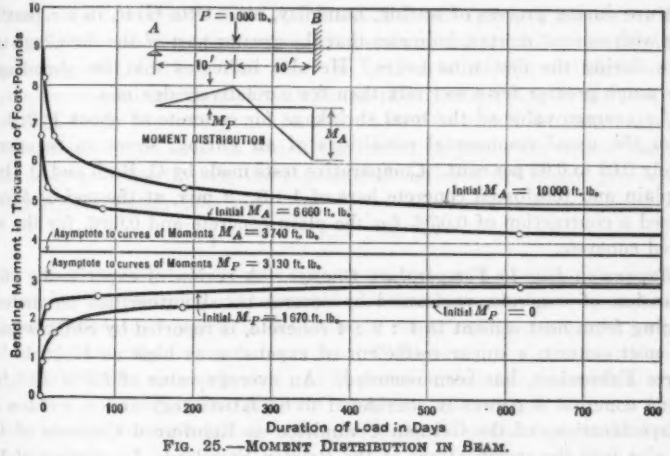

FIG. 25.—MOMENT DISTRIBUTION IN BEAM.

The graphs for the rate of change of the moment curve and point of contraflexure, of course, are subject to the criticism that the gradual changes in the moment curve have not been considered. Such progressive change can be accounted for by successive approximations and would result in the beam approaching a state of equilibrium more rapidly than is indicated by the diagrams. However, this refinement is not warranted with the present status of knowledge of the plastic properties of concrete.

## V.—ANALYSIS OF ARCHES

*Choice of Parameters in the Proposed Theories.*—Since no experimental studies of concrete have been made with the particular intention of fitting the results into theories such as the writer has proposed, it would be very strange, to say the least, to find many data which can be used directly to define numerically the parameters in the proposed equations. In general, the duration of the time-yield tests has been too short to give precise results. Usually, especially in foreign experiments, plastic flow has not been distinguished from shrinkage. In their studies of arches, the French simply combine the plastic flow and shrinkage into one effect, calling it *retrait*.

Nevertheless, since a study shows that plastic deformations on the one hand, and shrinkage and temperature deformations on the other, produce very different effects on the stresses in a structure, it becomes quite important that these properties be differentiated.

*Shrinkage of Concrete.*—Shrinkage is distinguished from plastic flow, in that it is a change in dimensions independent of external forces acting on the specimen.

The shrinkage of concrete varies within such wide limits that it is practically impossible, at present, to assign a definite value or law to its coefficient. Among the many factors[16] influencing this property are: The composition of the cement, quality of aggregate, proportioning of mix, wetness of mix, temperature during process of setting, humidity, etc. Otto Graf, in a report[17] on tests with cement mortar, indicates that the greater part of the shrinkage takes place during the first nine hours. He also indicates that the shrinkage is very much greater for a wet mix than for a relatively dry mix.

An average value of the total shrinkage for concrete of about 1:2:4 mix under the usual commercial conditions of air curing, seems to be approximately 0.02 to 0.03 per cent. Comparative tests made by C. Bach and O. Graf[18] on plain and reinforced concrete bars of 1 : 3 : 2 mix, at the end of 5 years, showed a contraction of 0.05% for the plain concrete and 0.02% for the reinforced concrete.

*Expansion Due to Temperature Change.*—A review of experiments on the expansion of concrete, performed by several noted authorities on materials ranging from neat cement to 1 : 2 : 4 concrete, is reported by Shitkewitsch.[19] For neat cement, a linear coefficient of expansion as high as $81 \times 10^{-7}$ per degree Fahrenheit, has been recorded. An average value of $55 \times 10^{-7}$ for a 1:2:4 concrete is generally considered to be satisfactory and is written into the specifications of the German Committee on Reinforced Concrete of 1925, and also into the specifications of the Belgian Standards Association of 1923. This value is corroborated in experiments by W. D. Pence, M. Am. Soc. C. E.[20]

Within the variation of the ordinary atmospheric temperatures, the coefficient of expansion is practically constant. Indeed, for the study of stresses in concrete arches, the coefficient of conductivity through the concrete is of tremendously greater importance than the variation found in the coefficient of expansion.

*Choice of Parameters for Exponential Formulas Defining Plastic Deformation in Arches.*—Although the exponents, $p$ and $q$, may vary considerably with concretes of various ages and qualities, the writer believes that they might be predetermined with a fair degree of precision by a systematic series of experiments. In a concrete which is not more than 2 weeks old, it appears that $q$ might be as low as 0.15, while $p$ might reach 2.0, or more. Concrete of a 1:2:4 mix subjected to a constant load beginning at about the age of

[20] *Journal*, West. Soc. of Engrs., Vol. VI, p. 549, 1901.

4 months, would probably deform according to the exponential equation with $q$ and $p$, respectively, equal to about 0.4 and 1.25.

From observations made on a large number of arches, E. Freyssinet, a French engineer who has developed mechanical methods of caring for rib-shortening effects in arches, gives values[21] for the shortening of a rib over a long period of time. The unit shortenings are listed for various cement contents as follows:

| | |
|---|---|
| 350 kg. per cu. m. (1.56 bbl. per cu. yd.)..... | $4 \times 10^{-4}$ to $6 \times 10^{-4}$ |
| 400 " " " " (1.78 " " " " )..... | $5 \times 10^{-4}$ to $7 \times 10^{-4}$ |
| 450 " " " " (2.00 " " " " )..... | $6 \times 10^{-4}$ to $8 \times 10^{-4}$ |

A curve representing the shortening over a long period of time would fluctuate above and below a mean which would slowly approach zero. The fluctuation, of course, is dependent on the temperature and humidity variations.

Assuming that, in the arches observed by Freyssinet, the shrinkage of the concrete due to setting was about 0.0003, the plastic shortening of the arch ribs made of the richer concrete would be about 0.0007 — 0.0003 = 0.0004. Hence, for an analysis of an arch in which the centering is moved within about 4 months after pouring the rib, the exponential equation for plastic flow would probably approximately take the form,

$$\epsilon = 17 \times 10^{-9}\, \sigma^{1.25}\, t^{0.4} \qquad (82)$$

in which, $\sigma$ is the stress, in pounds per square inch, and $t$ is the time, in days, after striking the centering. This would result in a plastic flow rib-shortening of about 0.00035 in 2 years, if the average dead load stress in the arch is 350 lb. per sq. in. According to Equation (82), it would require almost 10 years more to double this rib-shortening. It is probable that the exponential equation would take a somewhat different form as the concrete becomes older; however, no definite determination can be made from the experimental data now available.

The numerical parameters given in Equation (82) will not be strictly adhered to, in the studies which follow, but the constants chosen will be based on considerations similar to those just presented.

## Description of Arches Analyzed

*Description of Arch No. 1.*—Arch No. 1 is a symmetrical solid arch barrel having a rise ratio of 1:4. The center line of the arch is a parabola with a span of 140 ft., and a rise of 35 ft. from springing to crown. The thickness of the rib is 2 ft. at the crown and varies as the square of the secant of the angle between the tangent to the arch center line and the horizontal. Various assumptions have been made with regard to the properties of the material composing the arch. These variations will be explained when they are introduced into the discussion and the varied analyses are carried to completion. As far as possible, all variations are based on rational grounds which are borne out by experiment.

[21] "Le Pont de Villeneuve-sur-Lot," M. Freyssinet, *Le Genie Civil*, v. 79, p. 126, August, 1921.

*Description of Arch No. 2.*—Arch No. 2 is practically the same as Arch No. 1, except that the rise ratio is 1:8 instead of 1:4.

*General Analysis of the Arch.*—The arch rib (Fig. 26) is divided into twenty equal horizontal lengths, $\Delta x = 7$ ft. A point half way between the ends of each voussoir was located and numbered, the numbering being from left to right. Thus, Arch-Point No. 1 is a point on the center line of the arch, 3½ ft. horizontally to the right of the left springing; Point No. 2 is 10½ ft. horizontally to the right, etc. All distances are measured in feet.

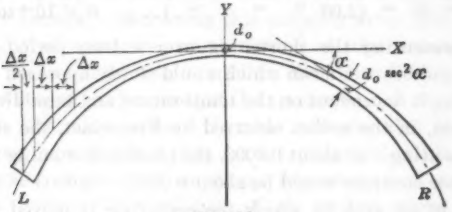

FIG. 26.

Deformations of the rib were found by computing the rate of angle change, $\frac{d\phi}{ds}$, and rate of rib-shortening, $\frac{d\xi}{ds}$, respectively, at each arch point, and assuming the total deformation within a voussoir to be concentrated at the corresponding arch point. Whenever possible, constant factors have been omitted from the computations, and introduced only where necessary to obtain relative results. In cases where logarithms were needed for numerical analysis, a constant factor was sometimes introduced to simplify the computation.

The center line of the parabolic arch with respect to the crown as the center of a rectangular co-ordinate system, is given by the equation,

$$y = \frac{2k}{x^2} \qquad (83)$$

in which, $k$ is a parameter equal to the distance from the focus to the directrix of the parabola, or twice the distance from the focus to the crown or apex of the parabola. For the arch having a rise ratio of 1:4 and a 140-ft. span, $k = 70$ ft. The co-ordinates of the arch points were computed by Equation (83).

The slope of the tangent to the center line of the rib at any point is the first derivative of $y$ with respect to $x$, hence,

$$\tan \alpha = \frac{dy}{dx} = -\frac{x}{k}$$

The cosine of the angle, $\alpha$, was read from a table of trigonometric functions. The thickness of the rib at any point is,

$$d = 2c = \frac{2c_0}{\cos^2 \alpha}$$

in which, $c_0$ is equal to one-half the crown thickness. Hence, since the thickness at the crown of the arch is 2, the vertical location of the neutral point, according to the ordinary theory of elasticity is,

$$y_c' = \frac{\sum_R^L \frac{y_c \Delta x}{E I \cos \alpha}}{\sum_R^L \frac{\Delta x}{E I \cos \alpha}} = \frac{\sum_R^L y_c \cos^5 \alpha \Delta x}{\sum_R^L \cos^5 \alpha \Delta x}$$

in which, $y_c$ is the distance from the crown of the arch to an arch point. The distance from the neutral point to an arch point is then,

$$y = y_c - y_c'$$

Table 1 contains the computations for the location of the neutral point and the co-ordinates of the arch points. Then, $y_c' = \frac{41.21}{5.893} = 7.00$.

## Studies of the Effects of a Variable Modulus of Elasticity on the Action of Arches

*Elastic Arch Uniformly Loaded and Rib-Shortening for All Causes.*—Consider a parabolic arch of the form, Arch No. 1. Fig. 27 shows the center line or axis of the arch, $L\,R$, as a solid line.

Suppose the arch to be uniformly loaded. Considering only flexural deformations in the arch, neglecting rib-shortening entirely, the line of pressure will be a parabola coinciding with the axis of the rib. Taking into account all causes except plastic flow, that is, elastic rib-shortening, temperature change, and shrinkage, there results a rid-shortening thrust, $H_{RS}$, which must act through the neutral point. Hence, at any point in the arch, the bending moment will be $M = H_{RS}\, y$.

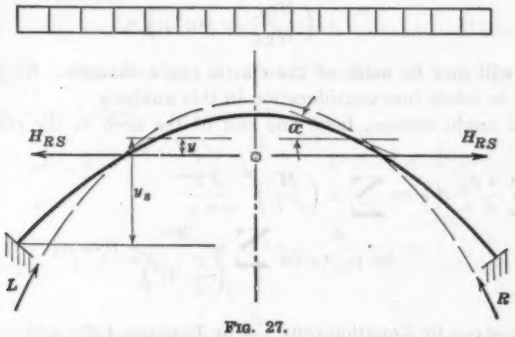

Fig. 27.

If $T_{DL}$ is the thrust due to the uniformly distributed load, the total thrust at any section of the rib is, $T = T_{DL} - H_{RS} \cos \alpha$.

The eccentricity of the thrust line will be,

$$z' = \frac{M}{T} = \frac{H_{RS}\, y}{T_{DL} - H_{RS} \cos \alpha} \qquad (84)$$

or,

$$z' = \frac{y}{\frac{T_{DL}}{H_{RS}} - \cos \alpha}$$

Since the arch is parabolic and uniformly loaded, the dead load thrust may be written in terms of the horizontal thrust,

$$T_{DL} = \frac{H_{DL}}{\cos \alpha} \quad \ldots\ldots(85)$$

TABLE 1.—COMPUTATIONS FOR THE LOCATION OF THE NEUTRAL POINT, AND CO-ORDINATES OF THE ARCH POINTS, FOR ARCH NO. 1

| Point. | $\Delta x$. | $x$. | $\frac{dy}{dx}$. | $\cos \alpha$. | $\cos^5 \alpha$. | $y_e = \frac{x^2}{2k}$. | $y_e \cos^5 \alpha$. | $y$. |

| Σ | .... | .... | ..... | ..... | 5.893 | .... | 41.21 | .... |

Taking into consideration that the thickness of the rib at any section is,

$$2c = 2c_0 \sec^2 \alpha \quad \ldots\ldots(86)$$

Equations (84), (85), and (86) may be combined to give the relation,

$$\frac{z'}{c} = \frac{y \cos^3 \alpha}{\left(\frac{H_{DL}}{H_{RS}} - \cos^2 \alpha\right) c_0} \quad \ldots\ldots(87)$$

A study will now be made of the elastic angle changes. No plastic deformations will be taken into consideration in this analysis.

The total angle change, from one end of the arch to the other, is represented by,

$$\sum \frac{d\phi_E}{ds} \Delta s = \sum k \left(\frac{M}{z'U}\right)^m \frac{\Delta x}{\cos \alpha}$$

$$= \frac{k}{b^m (c_0)^{1+2m}} \sum \frac{M^m}{\left(\frac{z'}{c} U'\right)^m} (\cos \alpha)^{1+4m} \Delta x \quad \ldots\ldots(88)$$

in which, $c$ is given by Equation (86), $\frac{z'}{c}$ by Equation (87), and,

$$U' = \frac{m}{1+m}\left[\left(\frac{w'}{c} + 1\right)^{\frac{(1+m)}{m}} - \left(\frac{w'}{c} - 1\right)^{\frac{(1+m)}{m}}\right]$$

which may be read from Fig. 10, showing the relation between $\frac{z'}{c}$ and $U'$.

Similarly, the horizontal movement of one springing relative to the other will be,

$$\Delta l = \sum \frac{d\,\phi_E}{d\,s}\, y_s\, \Delta s = \frac{k}{b^m\,(c_0)^{(1+2m)}} \sum \frac{M^m}{\left(\frac{z'}{c}\,U'\right)^m} (\cos\alpha)^{1+4m}\, y_s\, \Delta x \ldots (89)$$

in which, $y_s$ is the vertical distance from a line joining the springings to an arch point.

Assume that the rib-shortening thrust, $H_{RS}$, acts through the neutral point corresponding to the ordinary theory of elasticity. Table 2 indicates the computations for the eccentricity of the thrust line, the angle changes, and the relative horizontal movement of the springings, for the ratio, $\frac{H_{DL}}{H_{RS}} = 25$ and $m = 1$. The relations obtained from the proposed theory are used in making the analysis. For the special case in which $m$ is unity, Equations (88) and (89), respectively, become,

$$\sum \frac{d\,\phi_E}{d\,s}\, \Delta s = \frac{k}{b\,(c_0)^3} \sum \frac{M}{\frac{z'}{c}\,U'} \cos^5\alpha\, \Delta x \ldots\ldots\ldots (90)$$

and,

$$\Delta l = \frac{k}{b\,(c_0)^3} \sum \frac{M}{\frac{z'}{c}\,U'} \cos^5\alpha\, y_s\, \Delta x \ldots\ldots\ldots\ldots (91)$$

The elastic rib-shortening has not been included in $\Delta l$ in either Equation (89) or Equation (91). For convenience, the reciprocal of the factors, $\frac{k}{b^m\,(c_0)^{(1+2m)}}$, has been called $f$ in Tables 2 and 3. From Table 2,

$$\Delta l = -\frac{183}{144} \times 10^{-9}\,(961.2 - 356.7) \times 7 \times 2 \times H_{RS} = 0.00001075\, H_{RS}$$

Table 3 gives the angle changes and relative movement of the springings for the ratio, $\frac{H_{DL}}{H_{RS}} = 25$ and $m = 1.3$. Thus, Equation (88) and Equation (89), respectively, take the forms,

$$\sum \frac{d\,\phi_E}{d\,s}\, \Delta s = \frac{k}{b^{1.3}\,c_0^{3.6}}\, 10^{-0.2} \sum \left(\frac{M}{\frac{z'}{c}\,U'}\right)^{1.3} (\cos\alpha)^6 \times (10\cos\alpha)^{0.2}\, \Delta x \ldots (92)$$

and,

$$\Delta l = \frac{k}{b^{1.3}\,c_0^{3.6}}\, 10^{-0.2} \sum \left(\frac{M}{\frac{z'}{c}\,U'}\right)^{1.3} (\cos\alpha)^6 \times (10\cos\alpha)^{0.2}\, y_s\, \Delta x \ldots (93)$$

The computations have been carried out on the assumption that the neutral point, considering the modulus of elasticity a variable, coincides with the neutral point in which $m = 1$. Using the results of Table 3,

$$\Delta l = \frac{183}{(144)^{1.3}} \times 10^{-9}\,(4\,043 - 1\,465)\, 10^{-0.2} \times 7 \times 2 \times (H_{RS})^{1.3}$$
$$= 0.00000648\,(H_{RS})^{1.3}$$

It is realized, of course, from the experimental data on the elastic properties of concrete that a variable relation of stress to elastic strain in which $m$ is as high as 1.3 is probably never obtained in practice. However, an extreme value of $m$ has been chosen in order that the results may show characteristic trends more prominently. Also, since a value of $p$ of 1.3 in the proposed theory of plasticity is probably about correct for concrete 3 or 4 months old, this value makes a convenient starting point for an analysis in which the plastic properties of the material are considered.

A comparison of Tables 2 and 3 reveals some interesting phenomena. Both sets of computations were made on arches of identical dimensions and loadings, but of materials having very different elastic properties. In the first case (Table 2), Hooke's law was assumed to be true. This condition could have been solved by the ordinary theory of elasticity and the resulting differential angle changes, except for slight errors in precision, would have been identical with those obtained by an application of the proposed theory of elasticity, in which $m = 1$.

In both cases the rib-shortening thrust was considered to act in the same relative location. Although the rate of angle change at corresponding sections in the two arches differs greatly, the total angle change over the arch ring in both cases is practically equal to zero. However, change in span due to the rib-shortening thrust in the two cases varies, that for a constant modulus of elasticity being much less than that for a variable relation of stress to strain. For example, assume a uniformly distributed load to be placed on the arch of such a magnitude that the average compression at the crown is 200 lb. per sq. in. The rib-shortening thrust will be, $H_{RS} = 200 \times 12 \times 24 \div 25 = 2\,305$ lb. Hence, for $m = 1$, $\Delta l = 0.00001075 \times 2\,305 = 0.0248$ ft., and for $m = 1.3$, $\Delta l = 0.00000648 \times (2\,305)^{1.3} = 0.153$ ft.

As a result, assuming the coefficient of expansion in both arch materials to be constant and equal to each other, one might conclude that if the rib-shortening in the first case was due entirely to a temperature change of 36°, in the second case (a variable, $E$, being assumed) the temperature change which would cause the same stressed condition would be, $\Delta t° = 36° \times \frac{0.153}{0.0248} = 222°$. This comparison, however, is not entirely fair, because if one were solving an arch problem by the theory of elasticity he would probably choose a value of $E$ which would correspond to the secant modulus at the allowable working stresses, thus resulting in a different comparison. The foregoing comparison is based on the initial tangent modulus in both cases considered. Nevertheless, this analysis does indicate that temperature stresses computed by the ordinary theory of elasticity are incorrect.

### Analysis of Elastic Arch Subjected to a Uniformly Distributed Dead Load and Dead Load Rib-Shortening

Consider Arch No. 1 to be uniformly loaded. If there were no rib-shortening effects, the line of pressure would coincide with the axis of the rib and there would be no stresses due to flexure. However, the rib of the arch shortens under the load and, as a result, flexural stresses arise.

Neglecting all but elastic deformations, which is the case obtained at the instant of striking the forms of a newly constructed arch, the condition that there shall be no horizontal movement of the abutments is defined by,

$$\sum k \left(\frac{M}{z'U}\right)^m y \frac{\Delta x}{\cos \alpha} + \sum k \left(\frac{M}{z'U}\right)^m u' \Delta x = 0 \quad \ldots\ldots (94)$$

Since the moments are due entirely to the rib-shortening thrust, $H_{RS}$,

$$M = H_{RS}\, y$$

$y$ being the distance from the line of action of the rib-shortening thrust to the arch point considered. Equation (94) may thus be transformed into,

$$(H_{RS})^m k \sum \left(\frac{y}{z'U}\right)^m y \frac{\Delta x}{\cos \alpha} + (H_{RS})^m k \sum \left(\frac{y}{z'U}\right)^m u' \Delta x = 0 \quad \ldots (95)$$

An examination of Equation (95) indicates that the eccentricity of the line of thrust at any point is independent of the intensity of the thrust, for, by dividing the equation by $(H_{RS})^m$, it will be observed that every factor is independent of the stress in the arch. Hence, it may be concluded that $H_{RS}$ varies directly as the intensity of the dead load thrust, regardless of the values assigned to the parameters which define the properties of the material.

The problem now resolves itself into finding a ratio between the rib-shortening thrust and the dead load thrust which will give an eccentricity, $z'$, satisfying Equation (95).

*Solution for $m = 1$.*—When $m = 1$, which is merely the case of the ordinary theory of elasticity, the problem is most easily solved by transforming Equation (95) into the form,

$$H_{RS} \sum k \frac{y^2}{I} \frac{\Delta x}{\cos \alpha} + \sum k \frac{N}{A} \Delta x = 0 \quad \ldots\ldots\ldots\ldots (96)$$

but assuming absolute values for force vector,

$$N = - H_{RS} \cos \alpha + \frac{H_{DL}}{\cos \alpha}$$

Substituting this value into Equation (96), and re-arranging the terms,

$$\frac{H_{RS}}{H_{DL}} = \frac{\sum \frac{\Delta x}{A \cos \alpha}}{\sum \frac{y^2}{I} \frac{\Delta x}{\cos \alpha} + \sum \frac{\cos \alpha}{A} \Delta x} \quad \ldots\ldots\ldots\ldots (97)$$

Table 4 has been computed on the basis of Parabolic Arch No. 1, in which,

$$d = d_0 \sec^2 \alpha$$

hence,

$$I = \frac{1}{12} b\, d_0^3 \sec^6 \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (98)$$

and,

$$A = b\, d_0 \sec^2 \alpha$$

Thus, when Equations (98) are substituted into Equation (97), and making $d_0 = 2$,

$$\frac{H_{RS}}{H_{DL}} = \frac{\Sigma \cos \alpha\, \Delta x}{3 \Sigma y^2 \cos^5 \alpha\, \Delta x + \Sigma \cos^3 \alpha\, \Delta x} \quad \ldots\ldots\ldots\ldots (99)$$

From Table 4,

$$\frac{H_{RS}}{H_{DL}} = \frac{8.815}{3 \times 401.1 + 7.071} = \frac{1}{137.3}$$

The eccentricity of the thrust line at each arch point is given in Table 5.

| 4 | 7 | − 7.80 | 0.838 | 0.588 | 0.413 | 60.8 | 25.1 |
| 5 | 7 | − 3.60 | 0.876 | 0.673 | 0.518 | 12.96 | 6.7 |
| 6 | 7 | − 0.07 | 0.912 | 0.759 | 0.632 | 0.005 | 0.0 |
| 7 | 7 | + 2.72 | 0.944 | 0.840 | 0.748 | 7.40 | 5.5 |
| 8 | 7 | 4.82 | 0.970 | 0.912 | 0.856 | 23.2 | 19.9 |
| 9 | 7 | 6.24 | 0.989 | 0.967 | 0.945 | 38.6 | 36.5 |
| 10 | 7 | 6.91 | 0.999 | 0.997 | 0.995 | 47.8 | 47.5 |
| Σ | .. | ..... | 8.815 | 7.071 | ..... | ..... | 401.1 |

*Solution for $m = 1.3$.*—When the value of $m$ is other than unity, a solution becomes more cumbersome. For this case, the most convenient form of Equation (95) seems to be,

$$(H_{RS})^m \sum \frac{k}{b^m\, c^{1+2m}} \frac{y^m}{\left(\frac{z'}{c}\, U'\right)^m} y_s \frac{\Delta x}{\cos \alpha}$$

$$+ (H_{RS})^m \sum \frac{k}{b^m\, c^{2m}} \frac{y^m}{\left(\frac{z'}{c}\, U'\right)^m} \frac{u'}{c} \Delta x = 0 \ldots\ldots\ldots\ldots (100)$$

This relation takes the following form for both Arch No. 1 and Arch No. 2,

$$(H_{RS})^m \frac{k}{b^m\, (c_0)^{2m}}\, 10^{-0.2} \left[ \frac{1}{c_0} \sum \frac{y^m}{\left(\frac{z'}{c}\, U'\right)^m} y_s\, (10 \cos \alpha)^{0.2}\, (\cos \alpha)^6\, \Delta x \right.$$

$$\left. + \sum \frac{y^m}{\left(\frac{z'}{c}\, U'\right)^m} \frac{u'}{c}\, (10 \cos \alpha)^{0.2}\, (\cos \alpha)^5\, \Delta x \right] = 0 \ldots\ldots\ldots (101)$$

The requirement that the abutments shall not rotate is satisfied when,

$$(H_{RS})^m \frac{k}{b^m\, (c_0)^{1+2m}}\, 10^{-0.2} \sum \frac{y^m}{\left(\frac{z'}{c}\, U'\right)^m} (10 \cos \alpha)^{0.2}\, (\cos \alpha)^6\, \Delta x = 0 \ldots (102)$$

To obtain the correct line of thrust now resolves itself into finding the value of the ratio, $\frac{H_{RS}}{H_{DL}}$, and the location of the line of action of $H_{RS}$, which will satisfy Equation (101) and Equation (102).

Computations for Arch No. 1, in which $m = 1.3$, are shown on Table 6. The calculations are made on the assumption that the rib-shortening thrust is the same as that found for $m = 1$. It will be observed that the sum of the angle changes are practically equal to zero. However, considerable relative horizontal movement of the abutments is indicated. Consequently, one might conclude that the rib-shortening thrust lies in relatively the same line of action for the cases of constant $E$ and variable $E$, but that the magnitude of this thrust is the smaller in the case of the variable modulus. The line of action for the rib-shortening thrust, however, lies slightly higher for the case of the variable modulus, this being evidenced by the fact that the angle change in the arch rib portion above the assumed line of action of the rib-shortening thrust is slightly greater than the sum of the angle changes in the portion below. (See Table 6, Column (11).)

TABLE 5.—COMPUTATION FOR ECCENTRICITY, $\frac{z'}{c}$, DUE TO UNIFORMLY DISTRIBUTED LOAD ON ARCH NO. 1.

*Analysis for Arch No. 2.*—For Arch No. 2 the equation of the center line with reference to the crown as origin becomes, $y = \frac{x^2}{280}$ and $\tan \alpha = \frac{dy}{dx} = \frac{x}{140}$. Table 7 contains the computations for the location of the elastic neutral points. All distances are measured in feet. The constant factor, $\frac{3}{2} \frac{\Delta x}{b c_0^3}$, has been omitted from all partial elastic weights. Using the results from Table 7, $y' = \frac{41.63}{8.343} = 4.98$.

The ratio of the horizontal thrusts for rib-shortening and uniformly distributed load, and the corresponding eccentricity of the thrust line are calculated in Table 8, Columns (1) to (12), inclusive, on the consideration that $m$ is 1. From Table 8,

$$\frac{H_{RS}}{H_{DL}} = \frac{9.624}{3 \times 199.5 + 8.9} = \frac{1}{63.1}.$$

TABLE 6.—Relative Horizontal Movement of Cantilevers Terminating at Neutral Point Assuming Computed Line of Thrust for ($m = 1$) in Arch No. 1.

Columns (13), (14), and (15) have been added to compute the change in span length due to rib-shortening. The distances from the axis of the arch to the center of rotation of the section, which are given as $\frac{u'}{c}$ in Column (14), are taken from Fig. 9 for the corresponding values of $\frac{z'}{c}$ computed in Column (11). A check is thus obtained on the rib-shortening thrust by comparing the lengthening of the arch due to angle changes (the summation of Column (7)) and the shortening of the arch due to rib-shortening (the summation of Column (15)).

Computations for the relative displacements at the ends of the imaginary cantilevers connected to the arch springings and terminating at the neutral point, are given in Table 9 for the equilibrium polygon satisfying the ordinary theory of elasticity. The elasticity of the arch material is considered to satisfy the exponential stress-strain equation when $m = 1.3$. In this, as in Arch No. 1, the sum of the differential angle changes is practically equal to zero, although the lengthening due to angle changes (the summation of Column (12)) is greater than the shortening due to deformations along the axis of the rib (the summation of Column (14)).

In Table 10, calculations for angle changes and rib-shortening deformations were made considering that $\frac{H_{DL}}{H_{RS}} = 81.8$. It will be noticed that, for this ratio of the horizontal thrusts due to dead load and rib-shortening, respectively, the sum of the angle changes is practically equal to zero, and the change in span of the arch due to rib-shortening (summation of Column (15)) and the change in span due to angle changes (summation of Column (13)) are nearly equal in magnitude. Thus, since the line of thrust satisfies the conditions of statics and the geometric requirements imposed, it may be concluded that the line of thrust on which the computations in Table 10 are based, is correct.

* Since in Equation (87) the value, $\cos^2 \alpha$, causes only an inappreciable variation in $\frac{z'}{c}, \frac{H_{DL}}{H_{RS}} - \cos^2 \alpha$ was assumed to be constant and equal to 80.9.

† Interpolated.

Both Tables 8 and 10 indicate the eccentricity of the line of thrust at various points along the rib for Arch No. 2 under uniformly distributed vertical loading. For the case in which strain varies more rapidly than stress, that is, when $m = 1.3$ (Table 10), the line of thrust lies closer to the arch axis than when stress is considered proportional to strain, that is, when $m = 1.0$ (Table 8).

Studies similar to these have been made for non-uniform loading over an arch. In these investigations, which are not here included, it was found that, neglecting rib-shortening, the lines of thrust were practically identical for different values of $m$. Rib-shortening influences become greater for low than for high values of $m$.

## A Study of the Effect of Shrinkage

Arch No. 2 will be considered to be loaded with a uniformly distributed vertical load, and subject to plastic, elastic, and shrinkage deformations. The shrinkage will be assumed to be a definite function of the time, and the plastic flow will be considered to be a function of the time and stress intensity. In order to make the problem as simple as practicable it will be considered that no shrinkage causing internal stresses occurs until the centering supporting the newly constructed arch is removed. At that moment, all deformations are due to elastic distortions, and plastic and shrinkage deformations begin simultaneously. The problem, then, is to find the location of the line of thrust in the arch at the end of any time interval after striking the centering.

Consider the properties of the material to be defined by the exponential equations with the following parameters: $m = 1.3$; $p = 1.3$; $k = 183 \times 10^{-9}$; $K = 17 \times 10^{-9}$; and $q = 0.40$.

The eccentricity of the line of thrust at the crown when the structure is in equilibrium elastically before any plastic or shrinkage deformations have taken place, has been found to be $0.0611 \times 12 = 0.733$ in. With the stated conditions, since $m = p$ and neglecting shrinkage, there could be no movement of the line of thrust due to plastic flow.

Assume that the shrinkage is equal to,

$$\gamma = \eta\, t^q \qquad (103)$$

in which

$$\eta = 145 \times 10^{-7}$$

This would result in a unit shrinkage of about 0.0002 in two years.

The equations, stipulating, respectively, that the relative horizontal displacement of the springings and the total angle change in the arch rib shall be zero, may be written for Arch No. 2, as follows:

$$\frac{10^{-9.2}\,(183 + 17\,t^{0.4})}{(144)^{1.3}}\left[\sum\left(\frac{M}{\frac{z'}{c}\,U'}\right)^{1.3}(\cos\alpha)^6\,(10\cos\alpha)^{0.2}\,y_s\,\Delta x + \sum\left(\frac{M}{\frac{z'}{c}\,U'}\right)^{1.3}(\cos\alpha)^5(10\cos\alpha)^{0.2}\,\frac{v'}{c}\,\Delta x\right] - 140 \times 145 \times 10^{-7}\,t^{0.4} = 0. \qquad (104)$$

$$\frac{10^{-9.2}\,(183 + 17\,t^{0.4})}{(144)^{1.3}}\left[\sum\left(\frac{M}{\frac{z'}{c}\,U'}\right)^{1.3}(\cos\alpha)^{6}\,(10\cos\alpha)^{0.2}\,\Delta x\right] = 0 \quad \ldots\ldots (105)$$

Before any effects of shrinkage or plastic flow have taken place, the ratio of the dead load horizontal thrust to the rib-shortening horizontal thrust will be 81.8. This calculation has been indicated in Table 10. Since shrinkage takes place, one might well presuppose that the rib-shortening thrust will become greater. It will be considered, therefore, that the ratio, $\frac{H_{DL}}{H_{RS}}$, is equal to 71.8. Computations for the summations are shown in Table 11. By substituting these summations in Equation (105), and collecting the terms, the following numerical relation is obtained:

$$t = \left[-\frac{698}{64.7 - \frac{2\,090\,000}{H_{RS}^{1.3}}}\right]^{2.5} \quad \ldots\ldots (106)$$

Assuming that the uniformly distributed load causes an average thrust of 350 lb. per sq. in. at the crown,

$$H_{RS}^{1.3} = \left(350 \times 12 \times 24 \times \frac{1}{71.8}\right)^{1.3} = (1\,405)^{1.3} = 12\,400$$

and,

$$t = \left[-\frac{698}{64.7 - \frac{2\,090\,000}{12\,400}}\right]^{2.5} = 118 \text{ days}$$

The elastic change in length of span resulting from this rib-shortening thrust would be,

$$\Delta l = \frac{183}{(144)^{1.3}} \times 10^{-9}\,(1\,841 - 1\,477)\,2 \times 7 \times 10^{-0.2}\,H_{RS}^{1.3} = 674 \times 10^{-9}\,H_{RS}^{1.3}$$

For a load producing a crown thrust of 350 lb. per sq. in., the change in span length would be, $\Delta l = 674 \times 10^{-9} \times 12\,400 = 0.00836$ ft., or 0.100 in., which is extremely small.

To take shrinkage into account, it has been considered that the crown eccentricity of the thrust line would be a total of $0.0696 \times 12 = 0.836$ in., or $0.836 - 0.733 = 0.103$ in. greater than the normal eccentricity when the structure is in elastic equilibrium. As a result, of course, when the time interval, $t$, is zero, a slight horizontal displacement of the abutments ($\Delta l =$ 0.1 in.) is assumed. A period of 118 days, then, is the time which it would take for this horizontal displacement to become zero, considering that both plastic flow and shrinkage follow the assumed laws and that the average crown thrust is 350 lb. per sq. in. Thus, the eccentricity of the thrust line would become somewhat greater.

Consider, now, the case in which the denominator in the second member of Equation (106) is zero. That is,

$$64.7 - \frac{2\,090\,000}{H_{RS}^{1.3}} = 0$$

TABLE 11.—COMPUTATIONS FOR RELATIVE MOVEMENT OF SPRINGINGS OF ARCH NO. 2, WHEN UNIFORMLY LOADED AND

*Assumed that $\frac{H_{DL}}{H_{RS}} - \cos^2\alpha = 70.9$ since the greatest variation from this value is 0.1 and thereby causes an inappreciable effect.

† Interpolated.

or,

$$H_{RS} = \left(\frac{2\,090\,000}{64.7}\right)^{\frac{1}{1.3}} = 2\,920 \text{ lb.}$$

Then, the average dead load thrust at the crown will be,

$$\frac{H_{DL}}{12 \times 24} = \frac{2\,920 \times 71.8}{12 \times 24} = 728 \text{ lb. per sq. in.}$$

Thus, if the average thrust at the crown were 728 lb. per sq. in., or a total horizontal thrust of $728 \times 24 \times 12 = 210\,000$ lb., the rate of change of span length due to plastic deformation would be just equal and opposite to that due to shrinkage. As a result, $t$ becomes infinite.

If the properties of the concrete approximate those assumed for the analysis, the foregoing considerations make it difficult to conceive how shrinkage of the concrete can materially affect the stresses in the arch.

## Deflection of Crown of Arches

*General Equations.*—Fig. 28 indicates a loaded arch, the line of thrust being indicated by a full line.

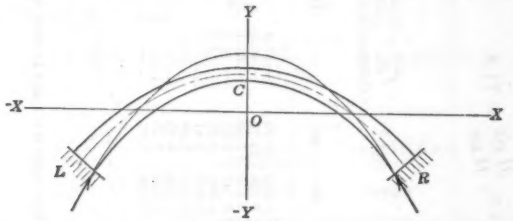

Fig. 28.

If the springing, $L$, does not rotate, the vertical deflection of the crown, $C$, must be,

$$\delta_c = \int_C^L \frac{d\,\phi}{d\,s}\,\frac{x\,d\,x}{\cos\alpha} + \int_C^L \frac{d\,\xi}{d\,s}\tan\alpha\,d\,x \quad \ldots\ldots\ldots (107)$$

regardless of whether the deformations are elastic, plastic, or a combination of both. Replacing the definite integrals of Equation (107) by finite summations, and considering only elastic deformations, the deformations following the relations,

$$\frac{d\,\phi}{d\,s} = k\left(\frac{M}{z'\,U}\right)^m, \text{ and } \frac{d\,\xi}{d\,s} = k\,u'\left(\frac{M}{z'\,U}\right)^m$$

there results the following equation for the vertical deflection of the crown of the arch:

$$\delta_c = k\sum_C^L \left(\frac{M}{z'\,U}\right)^m \frac{x\,\Delta\,x}{\cos\alpha} + k\sum_C^L u'\left(\frac{M}{z'\,U}\right)^m \tan\alpha\,\Delta\,x \quad \ldots\ldots (108)$$

If Hooke's law is considered to hold, Equation (108) may be rewritten in the form,

$$\delta_c = \sum_C^L \frac{M\,x\,\Delta\,x}{E\,I\cos\alpha} + \sum_C^L \frac{T\tan\alpha\,\Delta\,x}{E\,A} \quad \ldots\ldots\ldots\ldots (109)$$

In case both elastic and plastic deformations are considered, Equation (107) could be written as,

$$\delta_c = k \sum_C^L \left(\frac{M}{z'\,U}\right)^m \frac{x\,\Delta\,x}{\cos\,\alpha} + K\,t^q \sum_C^L \left(\frac{M}{z'\,V}\right)^p \frac{x\,\Delta\,x}{\cos\,\alpha}$$

$$+ k \sum_C^L u' \left(\frac{M}{z'\,U}\right)^m \tan\,\alpha\,\Delta\,x + K\,t^q \sum_C^L u' \left(\frac{M}{z'\,V}\right)^p \tan\,\alpha\,\Delta\,x \ldots (110)$$

If $n = p = m$, then $W = V = U$, and Equation (110) simplifies to,

$$\delta_c = (k + K\,t^q) \left[\sum_C^L \left(\frac{M}{z'\,W}\right)^n \frac{x\,\Delta\,x}{\cos\,\alpha} + \sum_C^L \left(\frac{M}{z'\,W}\right)^n w' \tan\,\alpha\,\Delta\,x\right]. \quad (111)$$

*Vertical Deflection of Crown of Arch No. 2 When Subjected to a Uniformly Distributed Vertical Load.*—Arch No. 2 is considered to be loaded with a uniform load of $w$ lb. per ft. of length. Tabular computations, not here included, based on the foregoing equations, were carried out to study the crown deflection due to rib-shortening effects when $m$ is equal to 1 and 1.3, respectively.

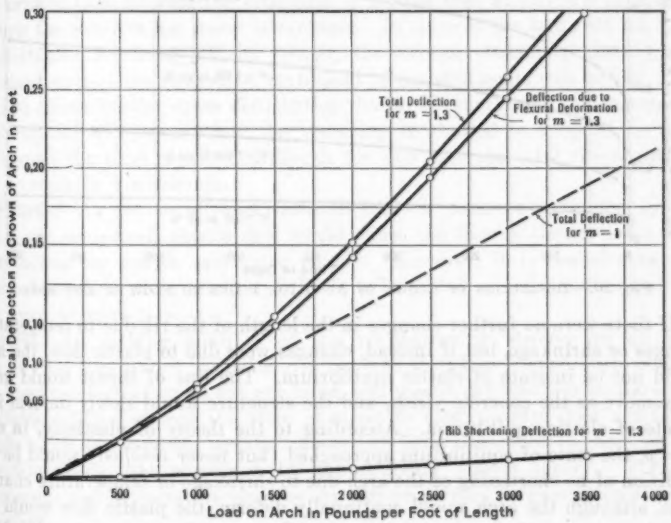

FIG. 29.—VERTICAL DEFLECTION OF CROWN OF ARCH NO. 2.

In order to have a basis for comparison of the deflection of the crown of an arch composed of a concrete following Hooke's law with one in which the exponential equation governs the relation of stress to strain, the parameters, $E$ and $k$, have been chosen so that the deflection will be the same for both arches when the average stress at the crown section is 300 lb. per sq. in.

In Fig. 29 are shown the crown deflections of the arch for various magnitudes of the uniformly distributed load. For the case of a variable modulus

of elasticity, several curves have been drawn; only the total deflection has been plotted for the arch in which material of construction is assumed to have a constant modulus of elasticity.

*Crown Deflection, Considering Plastic Flow.*—As a simple example of the anticipated effect of plastic flow on the crown deflection of an arch, Arch No. 1 is considered to be subjected to a uniformly distributed load and to be undergoing rib-shortening as well as temperature change. The following numerical values are used: $m = p = 1.3$; $k = 613 \times 10^{-10}$; $K = 56.7 \times 10^{-10}$; and $q = 40$.

It is considered that the ratio, $\frac{H_{DL}}{H_{RS}}$, is equal to 25. In this case, the rib-shortening force, $H_{RS}$, is due to all causes, including temperature change, shrinkage, and rib-shortening. The location of the resulting line of thrust is indicated in Table 2, together with computations for angle changes in the arch rib.

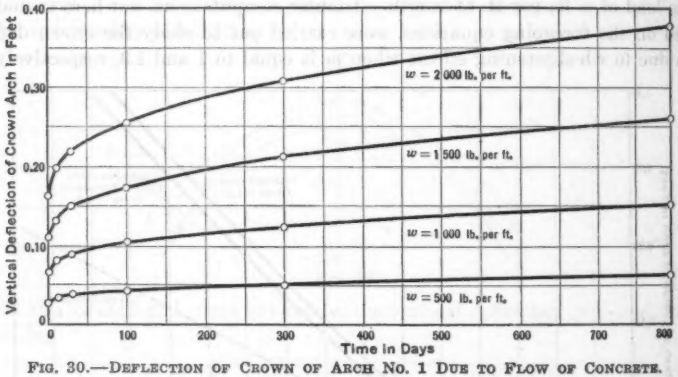

FIG. 30.—DEFLECTION OF CROWN OF ARCH NO. 1 DUE TO FLOW OF CONCRETE.

If there were no further changes in the length of the rib due to temperature changes or shrinkage, but if instead, changes were due to plastic flow, the arch would not be in state of elastic equilibrium. The line of thrust would gradually move as the concrete yields, and the structure would slowly deform into a state of elastic equilibrium. According to the theory of plasticity, in case $m = p$, the state of equilibrium approached (but never reached) would be the condition of no shortening of the arch due to shrinkage or temperature change. Thus, although the arch would continually deform, the plastic flow would act in such a way as to bring the structure back to its original state of equilibrium.

However, for simplification, and as a hypothetical case, the structure is supposedly held in elastic equilibrium by assuming that the temperature drops at such a rate that the tendency of the plastic flow to bring the structure to its original state of equilibrium is just offset by the reverse action caused by temperature change. As a result, the structure changes in shape although the relative location of the line of thrust and the stress distribution remains unchanged. In Fig. 30 are curves based on computations for various uniform load distributions over the arch.

## Conclusion

Inasmuch as the investigation presented in this paper is based on an impartial interpretation of physical facts regarding the behavior of concrete under sustained load, the writer feels justified in pointing out a few conclusions which appear unquestionable as a result of his study:

*First.*—It is incorrect to assume that in general plastic flow in statically indeterminate concrete structures causes a redistribution of bending moments tending to relieve the overstressed parts of the structure.

*Second.*—If there is an external disturbance encountered by a statically indeterminate concrete structure, such as the settlement of a support, the plastic flow causes a gradual redistribution of stresses such that the structure approaches (but never reaches) its original state of equilibrium (no settlement of support). When no external disturbances occur, plastic flow will cause progressive changes in the deflections and displacements of points on the structure, but will cause little or no change in the moment distribution. In this connection, temperature changes as well as rib-shortening and shrinkage in arches are included as external disturbances.

*Third.*—Provided disturbances due to reinforcing steel are not important, it is evident that striking the centering of a fixed arch at an early date after pouring the concrete has many advantages. In spite of the fact that the total rib-shortening resulting will be greater, the stresses occasioned thereby and in consequence of the immediate movement of the abutments will be less. The greatest effects on the stress distribution due to rib-shortening and movement of abutments will occur when the centering is allowed to support the arch far beyond the time required, although for this case the total rib-shortening will probably be a minimum.

*Fourth.*—As far as all experimental data on concrete examined by the writer are concerned, plastic flow would cause the line of thrust in an arch to approach the center axis more closely. However, it is conceivable that plastic flow might cause the line of thrust to be pulled away from the axis; this will occur when $m > p$.

*Fifth.*—In making analyses of the rib-shortening stresses in an arch it is of vital importance to distinguish between shrinkage, temperature change, and elastic deformation on the one hand, and plastic deformation on the other.

*Sixth.*—The fact that the ratio of stress to elastic strain does not follow Hooke's law for concrete usually causes but little difference in moment distribution from that computed by the ordinary elastic theory. For rib-shortening and temperature changes the difference may be greatly on the side of safety.

*Seventh.*—Stresses computed by the ordinary elastic theory for temperature changes are likely to be greatly in error, but on the side of safety for high temperature variations.

*Eighth.*—From the analyses of the crown deflections of an arch it appears well to sound a warning against misinterpretation of test data. The writer believes, especially for newly constructed arches, that, although the crown deflections measured in stressed arches may check computations made by the ordinary theory of elasticity in many cases, the location of the line of thrust

may be very different from that indicated by working back from the measured deflection by the usual theory.

The new theories presented in this paper are not intended to replace the ordinary method of analyses used heretofore, but are developed with the idea of supplementing the older theory of elasticity. For important statically indeterminate structures, such as long-span, fixed concrete arch bridges, an analysis seems incomplete without an investigation by more accurate methods than is provided by the usual theory in which stress is assumed to be proportional to strain and deformation due to flow is neglected. For smaller structures the usual procedure for stress analysis is probably satisfactory. The proposed methods serve further as tools for engineers in research and help to develop more accurate conceptions regarding the behavior of concrete structures.

Much more experimental work, especially of a quantitative nature, is desirable and necessary in order to establish definitely the laws of plastic flow for concrete of various mixes and ages.

# DISCUSSION

B. F. JAKOBSEN,[22] M. AM. SOC. C. E. (by letter).—The author presents a theory of bending in which the stress-strain relation of Equation (9), $\epsilon = k\,\sigma^m$, is substituted for Hooke's law, for which $m = 1$. As presented by the author, the constants, $k$ and $m$, are the same for tension as for compression.

The advantage of Hooke's law is its simplicity, as may be seen by comparing the ordinary formulas with those presented by the author; another advantage is that if it errs, as it does for high stresses, it errs on the side of safety. An analysis by the writer[23] of the test on the arch at Elevation 30 of the Stevenson Creek Dam shows that Cain's formulas, based on a constant modulus of elasticity, give stresses which agree well with the measured strains. In this case the stresses are fairly small and they are compressive throughout. An attempt to deal with the arch at Elevation 40 failed,[24] probably because the Cain formulas give considerable tension, and either cracks were produced or a shifting of the neutral axis took place, and possibly both phenomena occurred.

It appears to be a moot question whether or not Hooke's law applies for stresses well below the breaking stress, although scientific men have been occupied with a study of this phenomena for two centuries. Bulffinger proposed the exponential law in 1729 and Hodgkinson considered it in 1822. The parabolic law and recently the hyperbolic law have also been considered.[25] Bach states[26] that for compression of concrete, which has not been previously stressed, the deformations increase faster than the stresses. He gives various values for the coefficients, $k$ and $m$. Stanton Walker, M. Am. Soc. C. E., comes to the same conclusion[27] for concrete in compression. The late J. B. Johnson, M. Am. Soc. C. E.,[28] showed that for tension Hooke's law applies in general until near the breaking strength and states that the modulus of elasticity for stone concrete in tension is only 0.7 as great as in compression. Hool and Johnson give stress-strain curves for concrete in compression,[29] which show that Hooke's law applies for stone concrete up to a stress of more than 2 000 lb. per sq. in. at the age of 1 year. Messrs. Taylor and Thompson state that for compression the deformation curve is approximately a parabola, but that the modulus of elasticity is nearly constant for about one-third the ultimate strength, that is for all normal working stresses.[30] The modulus for tension, they state, is probably the same as for compression, though but few tests have been made. Tests by Mörsch indicate that for concrete the defor-
